

Correcting for Restriction of Range in Both X and Y When the Unrestricted Variances are Unknown

Ralph A. Alexander, Paul J. Hanges, and George M. Alliger
The University of Akron

Correction of correlation coefficients that have arisen from range restricted populations is commonly suggested and practiced in research on testing and measurement. Until recently, that research has operated under two important limitations. First, the majority of the research has dealt with range restriction on one variable only, and second, the correction formulas have assumed that the variance of the variable(s) in

the unrestricted population was known. This article presents a method for estimating such corrections from the data in the restricted sample and applies the method to a recently developed approximation for restriction on both X and Y . The procedure is evaluated and found to produce sufficiently accurate results to be useful in many practical range restriction settings.

The theoretical and applied research on correlation coefficients that have been affected by range restriction has grown to a sizable body of literature since the problem was first summarized by Pearson (1903). Until recently, most of this research has suffered from two limitations. First, the correction of coefficients for range restriction has been limited almost entirely to formulas that assume restriction on only a single variable. Second, such corrections have been applied under the assumption that the unrestricted population variance of one or more of the variables of interest is known or can be reasonably estimated from some source other than the sample data itself.

The correction of sample r s for range restriction is by now a widely accepted practice in the psychological testing and measurement literature (American Psychological Association, Division 14, 1980), and such corrected correlations have generally been found to be less biased than the uncorrected values, even under a variety of assumption violations (Linn, 1983). The most frequently used correction formulas have been researched since the early 1920s (Kelley, 1923; Otis, 1922), but were brought into more common use by Thorndike (1947). These correction formulas (usually referred to in the psychological literature as the Thorndike Case 1, Case 2, and Case 3 formulas) are only applicable for correcting the X - Y correlation when restriction has occurred on either X or on Y or on some third variable.

To date, very little consideration has been given to the problem of correlations that have arisen from distributions restricted on both X and Y . Although Pearson (1908) provided a partial solution to this problem, it is only recently that further advances have been made. Weiler (1959) and Regier and Hamdan (1971) developed the mathematics for calculating the range-restricted correlation from properties of the

unrestricted distribution and the extent of truncation on X and Y . However, an exact expression for correcting the range-restricted correlation has not yet been found (Regier & Hamdan, 1971). Wells and Fruchter (1970) presented an approximate correction procedure for this case, and the procedure has been found to perform reasonably well (Alexander, Carson, Alliger, & Barrett, 1984). Alexander, Carson, Alliger, and Carr (1984) derived an improved approximation which they reported yields corrected values within $\pm 1\%$ of the true population values under a wide variety of cuts on both X and Y . That approximation formula is:

$$r = \frac{r'^2 - 1}{2r'} U_x U_y \pm \left[\frac{(1 - r'^2)^2}{4r'^2} U_x^2 U_y^2 + 1 \right]^{1/2}, \quad (1)$$

where r' is the range-restricted correlation, U_x and U_y are the ratios of restricted to unrestricted standard deviations in X and Y , respectively (e.g., $U_x = S'_x/S_x$), and

the " \pm " sign takes the sign of r' .

As is the case in the Thorndike corrections for unidimensional range restriction, Equation 1 requires knowledge of the unrestricted standard deviations (e.g., S_x) of both variables. Virtually all of the prior literature on restriction of range has estimated this value from population norms or from assumed values of the truncation point on the variable (see, e.g., Alexander, Carson, Alliger, & Barrett, in press; Sackett & Wade, 1983; Schmidt, Hunter, & Urry, 1976). Recently, Alexander, Alliger, and Hanges (1984) noted that, at times, such information is not available, and they reported a procedure for estimating the unrestricted standard deviation directly from the restricted sample data when restriction has occurred on one of the two variables of interest (X or Y). They reported that the procedure is quite accurate in recapturing the underlying correlation and that the sampling variance of such corrected rs is only slightly greater than that of rs corrected under the assumption of a known population variance.

The purpose of this article is to extend the Alexander, Alliger, and Hanges (1984) method to the estimation of unrestricted standard deviations in both X and Y when both variables are truncated. These values are then applied to Equation 1, and the accuracy and sampling variance of the corrected rs is examined.

Method

Cohen (1959) showed that for a sample drawn from a bivariate normal X - Y distribution truncated, for example, on X , there is a unique sample statistic that will provide information about the restriction. This is referred to as Cohen's Ratio (CR):

$$CR_x = S_x'^2 / (\bar{X} - X_c)^2, \quad (2)$$

where $S_x'^2$ is the variance,

\bar{X} is the mean, and

X_c is the lowest observed value,

all observed on X in the restricted sample. (Throughout this discussion it is assumed that truncation has occurred from below. If truncation occurs from above, the highest rather than the lowest observed value would be used.) Alexander, Alliger, and Hanges (1984) tabled two functions of the truncated normal distribution of X and used these tabled values to correct for unidimensional truncation. The two functions are the z -score representing the truncation point and the standard deviation of X in standardized form in the restricted distribution.

The extension of this method to bidimensional truncation (restriction on both X and Y) is straightforward. Cohen's Ratio on Y becomes:

$$CR_y = S_y'^2 / (\bar{Y} - Y_c)^2 \quad (3)$$

For any given pair of cutting scores z_x on X and z_y on Y , there will be a unique pair of CR s and standardized standard deviations. Since each of the restricted standardized standard deviations represents the proportional reduction in the standard deviation due to range restriction, each is equal to the ratio of the restricted to unrestricted standard deviation—that is, U_x and U_y .

In order to use this method, then, it is necessary to first construct a table of these values. In testing the method for this study, a computer program was written that constructed such a table for all possible combinations of cuts on X and Y ranging from -2σ to $+2\sigma$ in increments of $.10\sigma$. For each pair of truncation points, the values of CR_x , CR_y , U_x , and U_y were calculated. Since that table is far too lengthy to reproduce here, selected values are shown in Table 1.

The range restriction correction method proceeds as follows. From the empirical sample at hand, calculate r_{xy} , and CR_x , CR_y (from Equations 2 and 3). Find the pair of tabled CR values ($CR_{(TAB)}$) that is closest to the pair of CR values calculated from the sample ($CR_{(OBS)}$). This is done by finding the pair of tabled values that minimizes the sum of the squared differences (i.e., $\text{MIN}[(CR_{x(OBS)} - CR_{x(TAB)})^2 + (CR_{y(OBS)} - CR_{y(TAB)})^2]$). (A computer program is available from the first author that constructs the described table, calculates the sample values needed, finds the minimum function and displays the associated values.)

.622	.622	.502	.502	1.0	1.0

Once the closest pair of tabled CR values is found, the U_x and U_y values associated with that pair are used in Equation 1.

The performance of this method was tested with computer simulations. Using the *IMSL Library* (1979), bivariate normal samples were generated for $\rho = .2, .4, .5, .6,$ and $.8$; n -sizes of 30, 60, and 100; and truncation points on X and Y of $z = -2, -1, 0,$ and $+1$. Each simulation was run with 2,000 random samples. For each random sample r_{xy} , CR_x , and CR_y were calculated, the closest pair of tabled values of CR was found and Equation 1 used to compute the corrected r .

The algorithms needed to calculate CR_x , CR_y , U_x , and U_y under bidimensional truncation are reported elsewhere (Alexander, Carson, Alliger, & Barrett, 1984, in press) and in the interest of brevity are not repeated here. Those algorithms require knowledge of the underlying unrestricted population ρ in order to compute functions of a bidimensionally truncated distribution. The simulations reported here all used an assumed value of $\rho = .50$. These simulations were repeated for several other values of ρ and the results were very similar. This is due to the fact that the CR and U values vary only slightly as a function of ρ except for extreme ρ (approaching .05 or .95).

Results and Discussion

Table 2 contains the mean observed and corrected correlations as a function of ρ and truncation points for sample sizes of 60. Under moderate truncation on both variables, the procedure overcorrects slightly (maximum mean overcorrection is .02); however, this tendency decreases as the population ρ increases. If only one variable is severely truncated while the other is moderately restricted, the procedure is again relatively accurate (maximum mean deviation is $-.04$). The procedure tends to show maximum overcorrection when the population ρ is close to .50. However, in general, as the truncation on one variable becomes more severe and as the population ρ approaches .80, the procedure undercorrects. In the case of extreme restriction on both variables, the procedure consistently undercorrects (maximum mean undercorrection is $-.06$); the severity of this undercorrection diminishes, however, as the population ρ increases.

Thus, the procedure outlined in this paper accurately recaptures, on the average, the true population ρ for sample sizes of 60. The results were comparable for the simulations with sizes of 30 and 100, though the maximum mean deviation from the true ρ did differ (maximum mean deviation for $n = 30$ was $-.11$, maximum mean deviation for $n = 100$ was $-.04$). The method overcorrects for slight truncation and low ρ and overcorrects for severe restriction on both variables and low ρ .

Table 3 presents the standard deviations for the uncorrected correlations, the corrected correlations when the population variance is known, and the corrected correlations when the population variance is estimated with the present procedure for varying truncation points, population ρ , and sample sizes. Although the current procedure does increase the standard deviations above those for the observed uncorrected correlations, these values are only slightly greater for the proposed method than when the population variance is assumed to be known. In fact, the maximum inflation of the standard deviation is only .07 for $n = 30$, .05 for $n = 60$, and .04 for $n = 100$. When $\rho = .80$, the mean standard deviations for the correction formulas are almost equal to those for the uncorrected correlations. Thus, the present procedure not only adequately corrects correlation coefficients in the more common case when the population variance is unknown, but it does so with a minimal increase in variability from currently used procedures when knowledge of the population variance is necessary.

Conclusions

This paper extended the Alexander, Alliger, and Hanges (1984) univariate restriction of range correction procedure to the bidimensional case. The results of the simulations indicate that correction for

correlations when the population unrestricted variances are unknown may be useful. These results will, of course, strictly hold only for bivariate normal distributions under conditions of strict truncation. Further research is needed to determine the robustness of the procedure under violations of these assumptions. The accuracy of this new procedure appears to be comparable to the currently used procedures that assume knowledge of the unrestricted population variances.
