Acknowledgements

I have had the incredible fortune to be influenced professionally and personally by many mentors. It has been the opportunity of a lifetime to work closely with Paul Sackett, who has set such an incredibly high bar as an adviser, collaborator, and friend. I would like to thank each member of my committee, namely John Campbell, Aaron Schmidt, and Mark Davison, as well as Nathan Kuncel and Deniz Ones for contributing so much to enrich my education and experience.

Steve Nichols and Jeff Foster deserve major acknowledgement for playing key roles in my dissertation research.

Patrick Sharpe, Tom Kane, Chuck MacLane, and Carol Shoptaugh all provided guidance and opportunities that I will always appreciate. In addition, all of my colleagues and friends from the University of Minnesota, U.S. Office of Personnel Management, and Missouri State University deserve hearty thanks.

I would like to thank Renee Vincent, my parents, and brothers for their encouragement and support. Most importantly, thanks to Renee for being my partner and secret weapon in all my endeavors.

Abstract

This research examines the form of the relationship between Big Five-oriented personality predictors and occupational performance throughout the predictor and criterion score ranges. Building on rationale that individuals can be either “too low” or “too high” in their standing on various personality attributes for optimal performance, previous research has produced discrepant findings with regard to whether and when to expect curvilinear relationships between these attributes and job performance. Previous studies have relied on small samples and unsystematic sampling, a variety of performance criteria, the use of personality inventories for which construct validity evidence is not immediately available, and a focus on only one or two of the Big Five personality factors (typically conscientiousness). If personality—performance relationships exhibit nonlinearity within the score range where decisions are made, there could be immediate implications for the inferences that could be drawn from the use of such test scores, such as whether top-down or cutoff-score based uses are most appropriate. Incorporating large sample ($n > 11,000$) operational personality and performance data, this research had several goals: (a) replicate and extend previous research on conscientiousness and emotional stability to clarify existing conflicts in findings, (b) provide the first major tests of nonlinearity for agreeableness, openness, and extraversion, and (c) use a theoretically linked framework to identify and test for relevant occupation-level moderating variables by incorporating job complexity and personality based job analytic information. Results showed a general lack of meaningful curvilinear effects for each Big Five scale in relation to overall job performance. Any expected

declines in performance at high ends of the predictor range were very small on average, and would be highly unlikely to produce scenarios in which those passing a realistic cut score would be expected to underperform those screened out due a curvilinear effect. Indices of job complexity and the importance of the personality trait to performance did not exhibit moderating effects for the forms of each personality—performance relationship. Results are useful for evaluating whether nonlinearity is likely to be an issue when self-report personality assessments are used to make decisions with tangible employment consequences. Even with slight curvilinear trends for several of the scales examined, the results suggest that curvilinearity is highly unlikely to present problems for typical uses of personality test scores in employment settings.

INTRODUCTION

In the years following 1991, researchers have generally accepted personality characteristics as a class of individual differences for understanding individual behavior in the workplace. In the psychology literature, concepts of personality have been integrated into theory and practice in topics such as personnel selection (Hough & Johnson, 2013), job analysis (Raymark, Schmit, & Guion, 1997), leadership (Judge, Bono, Ilies, & Gerhardt, 2002), team performance (Peeters, Van Tuijl, Rutte, & Reyman, 2006), and job satisfaction (Judge, Heller, & Mount, 2002). A major emphasis has been placed on understanding predictive relationships between personality characteristics and job performance measures (Bartram, 2005; Hogan & Holland, 2003). Despite this emphasis, much work remains in investigating the form of the relationships between personality measures used in employment testing and indicators of valued job performance. The current evidentiary base on these relationships has led to both enthusiastic support (Ones, Dilchert, Viswesvaran, & Judge, 2007) and prominent criticism (Morgeson, Campion, Dipboye, Hollenbeck, Murphy, & Schmitt, 2007) of personality assessment in the workplace. One question that both sides seem to consider important is whether there is reason to expect nonlinear personality—performance relationships, as the answer would affect conclusions about how personality assessment scores should be used and how well they can predict subsequent behavior. To date, almost all of the research on personality testing in employment settings is based on the either explicit or implicit assumption that personality—performance relationships are

linear. The purpose of this dissertation is to explore the degree to which this assumption holds.

As the practice of personality assessment in the workplace has gained prominence, the possibility of nonlinear personality—performance relationships has been incorporated into burgeoning theory. The fundamental idea is that individuals could be both “too low” or “too high” for optimal performance in their standing on various personality attributes. For the purposes of this dissertation, *nonlinear* refers to a class of relationships between independent and dependent variables. In straightforward language, these nonlinear relationships are characterized by having a line of best fit, or regression line, that is not straight throughout the score ranges of both variables. Best fitting nonlinear relationships may form “U”, “inverted-U”, or even more complex shapes. Mathematically, they can be defined by examining variables above an order of unity, such as quadratic or cubic variables. In a regression framework, these nonlinear relationships can be said to be nonlinear in the variables but linear in the parameters, in the sense that the fundamental regression equations involve additive effects among independent variables to best predict a dependent variable (Cohen, Cohen, West, & Aiken, 2003, p. 195). Several scholars have suggested that aspects of the five-factor (or “Big Five”) model, which is the dominant personality taxonomy in I-O psychology, might be related in a nonlinear fashion to job performance (Le, Oh, Robbins, Ilies, Holland, & Westrick, 2011; Murphy, 1996; Ones et al., 2007). However, current theory omits several of the major components of the Big Five, and few aspects of the posited nonlinear relationships have been empirically investigated. Thus, in addition to

contributing to an understanding of the observed form of personality—performance relationships, this dissertation adds to theory on the expected relationships between aspects of personality and job performance.

The presence of robust nonlinear personality—performance relationships may have implications for applied settings in which personality assessments are used to make administrative decisions about job applicants or incumbents. As noted by both Hough and Dilchert (2010) and Converse and Oswald (2012), in instances where individuals are rank-ordered on the basis of personality assessment scores, certain forms of nonlinear relationships may result in errors of inference regarding the expected performance associated with a given personality score if linearity is assumed. In cases where personality assessment scores define a minimum threshold for screen out or screen in purposes (e.g., Berry & Sackett, 2009), in the presence of substantial curvilinearity, those who pass a cut score could perform the same or worse than those who were rejected, on average. Information about nonlinear relationships may be used to identify optimal cut points in the distribution of personality scores. Thus, the fundamental assumption that “higher standing is better” in the personality domain has been challenged on conceptual grounds, and if borne out empirically, could have important consequences for the use of personality assessments in employment settings. Empirical work examining these issues to date has yielded inconsistent findings and has suggested the presence of moderating factors. That is, previous research has produced discrepant findings with regard to whether and when to expect nonlinear relationships between these attributes and various measures of individual job performance. Though previous research has suggested

moderators of the magnitude of personality—performance relationships (Barrick & Mount, 1993), very few authors have proposed that the *form* of these relationships may be dependent on moderating factors (cf. Le et al., 2011). Tett and Burnett (2003) offered a framework for identifying and examining such moderators, but this framework has not been applied to studies of the form of personality—performance relationships. Thus, an additional goal of this dissertation is the examination of large-scale personality assessment and job performance data to examine whether personality—performance relationships are best described as nonlinear, and identification of the conditions under which, if any, nonlinearity is present.

This document is organized as follows. The first section includes background information and a literature review. This section begins by reviewing the use of personality assessment in organizations as a tool for human resource decisions. The focus is directed toward issues relevant to the form of the relationship between aspects of personality and job performance. The review then moves to the basis for an examination of the presence of nonlinearity in personality—performance relationships. This discussion focuses on psychological theory-based perspectives as well as issues of applied personality measurement in organizations. Then empirical work that examines the form of personality—performance relationships is reviewed, highlighting issues that prevent clear inferences from being drawn from the existing results. This section concludes with a description of the current study as a contribution to the literature. A statement of research questions forms the culmination of this section.

The second section describes the methodology used to examine the research questions. Here, the sample and analytic framework used to evaluate the research questions are described. The third section describes the results of the focal analyses. The fourth section contains a discussion of implications of the findings and study limitations.

SECTION 1: LITERATURE REVIEW

Defining Personality as the Domain of Interest

The purpose of this section is to define personality as the focal domain of individual differences in this dissertation. As Murphy (1996) notes, the term *personality* has been defined in many ways, and it is not always clear how aspects of personality differ from cognitive abilities, interests, moods, or values (cf., Barrick, Mount, & Gupta, 2003; DeYoung, 2011). Major taxonomic work has been achieved in these domains, and a complete review of all domains is beyond the scope of this dissertation. In this section, I review fundamental definitions of personality and its distinction from the cognitive ability domain. I also address the taxonomic structure of the personality domain, especially as it relates to the variables of interest in the current study.

To begin, McAdams and Pals (2006) provide the following as a definition of the personality domain:

Personality is an individual's unique variation on the general evolutionary design for human nature, expressed as a developing pattern of dispositional traits, characteristic adaptations, and integrative life stories complexly and differentially situated in culture. (p. 212)

Following Tett and Guterman (2000), Tett and Burnett (2003) define personality as:

Intraindividual consistencies and interindividual uniqueness in propensities to behave in identifiable ways in light of situational demands. (p. 502)

From a trait perspective, the term *personality* is typically used to describe a set of dispositional characteristics that are stable enough to be viewed as a driver of an individual's tendency to behave in a particular manner. While there is broad recognition that momentary states can influence an individual's thoughts, feelings, and actions (Fleeson & Gallagher, 2009), personality traits have been shown to predict many valued behaviors and life outcomes such as happiness, health, relationship quality, and occupational attainment and performance (Ozer & Benet-Martinez, 2006; Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). While personality can be viewed in terms of both trait and state aspects, this study focuses on the stable aspects of personality that are commonly used to inform administrative decisions in employment settings.

Personality-based characteristics are often distinguished from the domain of cognitive abilities (Gottfredson, 1997; Neisser, Boodoo, Bouchard, Boykin, Brody, Ceci, Halpern, Loehlin, Perloff, Sternberg, & Urbina, 1996). The label *noncognitive* is often applied to the personality domain, whereas intelligence and general mental ability are placed in the domain of *cognitive* abilities. Gottfredson (1997) defines intelligence as follows:

Intelligence is a very general mental capability that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It is not merely book learning, a narrow academic skill, or test-taking smarts. Rather, it reflects a broader and

deeper capability for comprehending our surroundings—“catching on”, “making sense” of things, or “figuring out” what to do. (p. 13)

While Carroll (1993) summarized nearly 100 years of empirical work in an enormous set of analyses that yielded the generally accepted three-stratum model of cognitive abilities, it is certainly the case that debate continues on the nature of cognitive ability and its consequences for policy (Neisser et al., 1996; Nisbett, Aronson, Blair, Dickens, Flynn, Halpern, & Turkheimer, 2012). Recognizing that the distinction between the noncognitive/cognitive labels can be unsatisfying (DeYoung, 2011), one way of delineating the personality constructs examined in this study is to say that they are major components of the noncognitive construct space and do not appear in taxonomic structures such as that offered by Carroll (1993).

Relative to the cognitive domain, work on the structure of personality has begun much more recently. Current concepts of the structure of personality can be traced through two major traditions. The first is often referred to as the *lexical hypothesis* (John & Srivastava, 1999). This perspective is based on the notion that personality descriptors can be found in language (Allport & Odbert, 1936). Specific focus is placed on words developed to describe personal characteristics and tendencies. The lexical hypothesis states that the general structure of personality attributes can be identified based on the degree to which the terms covary when used to describe one’s self or other people (Saucier & Goldberg, 2001). The second tradition involved the placement of personality-based descriptors on questionnaires. Questionnaires were then distributed to thousands of respondents across many different cultures (McCrae & Costa, 1997). Data from

personality description questionnaires, many of which included terms drawn from the lexical hypothesis, has provided robust evidence for a *Five Factor Model* of personality (Digman, 1990; John & Srivastava, 1999; McCrae & Costa, 1997). Barrick, Mount, and Judge (2001) offer a series of adjectives intended to describe the five factors: (a) *conscientiousness* involves being dependable, achievement-striving, hardworking, persevering, and orderly; (b) *agreeableness* involves being cooperative, flexible, tolerant, and forgiving; (c) *emotional stability* involves being calm, self-confident, and resilient; (d) *extraversion* involves being sociable, talkative, assertive, and active; and (e) *openness to experience* involves being curious, broad-minded, intelligent, and cultured. The five factor, or *Big Five*, model of personality has served as an important framework for integrating research on the internal structure and nomological network of human personality. Still, skepticism exists about the degree to which the Big Five can be used to comprehensively summarize individual differences in personality (Block, 1995; Hough, 1992). Nonetheless, some critics at least agree that the Big Five framework represents a useful tool for organizing research and identifying prospects for future inquiry (Hough & Schneider, 1996).

In addition, the hierarchical structure of the personality domain is currently thought to be at least as theoretically and empirically complex as the cognitive ability domain. Part of the reason for this is that measured personality attributes do not exhibit the degree of positive manifold that measures of disparate cognitive abilities do (Murphy, 1996; Schmidt, 2012). Among personality researchers, consensus is emerging that the structure of personality can best be described as a multi-level hierarchy (Markon,

Krueger, & Watson, 2005; Ones, Viswesvaran, & Dilchert, 2005). Given either non-zero correlations among the Big Five factors or trait profiles across the factors, researchers have identified broad, higher-level traits defined by combinations of Big Five factors. These combinations, or meta-traits, have been given different labels by different researchers. The combination of conscientiousness, agreeableness, and emotional stability form a higher-order factor termed *alpha* (Digman, 1997), *stability* (DeYoung, 2010), or *integrity* (Ones & Viswesvaran, 2001) depending on its use. Similarly, the combination of extraversion and openness to experience is termed *beta* (Digman, 1997) or *plasticity* (DeYoung, 2010). Conversely, each Big Five factor can be further split into facets or subscales. Facets are said to be related to their overarching Big Five factor, but may also exhibit differing patterns of empirical relationships with external variables (Dudley, Orvis, Lebiecki, & Cortina, 2006). Although a generalizable structure of Big Five subfacets has not yet been established, structures of these facets are available for some personality measures (e.g., Costa & McCrae, 1995). Since many studies summarize predictive relationships between Big 5-level personality characteristics and various behavioral criteria, and the Big Five reside at a conceptual level of broad use in employment settings, the hierarchical level of personality corresponding to the Big Five will be the focus of this dissertation.

Socioanalytic theory is another view of the personality domain that has led to conceptual and empirical support for the Five Factor Model (Hogan, Hogan, & Roberts, 1996). Hogan and Shelton (1998) and Hogan, Davies, and Hogan (2007) describe socioanalytic theory, which posits that individuals have two key motivations: *getting*

along and *getting ahead*. Getting along refers to functioning effectively with others in society, while getting ahead refers to gaining power and status. These motivations shape the two primary socioanalytic perspectives on describing personality: external description as one's *reputation*, and internal description as one's *identity*. Moving beyond the self-descriptions reported by McCrae and Costa (1997), Hogan and Shelton (1998) discuss how the Big Five has been recovered in studies of reputations—that is, studies that involve observer ratings of personality. The primary point is that when the aforementioned literatures are taken together, the Big Five structure has emerged from studies of both self and observer reports in many different contexts.

The goal of this discussion is to set the stage for personality as the focal domain of interest in this dissertation. The next section describes how personality concepts and measures have been integrated into research on work behavior.

Personality Measurement in Industrial and Organizational Psychology

Historically, individual differences related to personality, temperament, and dispositional concepts were used in various applied psychology interventions. For instance, in addition to job-related skills and abilities (Dunnette, 1976), applied psychologists and human resource professionals have a long history of evaluating applicant noncognitive characteristics, particularly for managerial occupations (Bray & Grant, 1966; Guion, 1967). These characteristics, such as “interpersonal skills”, “integrity”, “attention to detail”, or “resistance to stress”, can be crosswalked to personality-based concepts. However, the lack of a common framework and a proliferation of measures led to a fragmented research literature from which few

generalizations could be made (Guion & Gottier, 1965). At the same time, reviews of available data from personality instruments revealed no systematic pattern for the usefulness of predicting job performance, the most relevant set of dependent variables for I-O psychologists (Guion & Gottier, 1965). Additionally, the range of occupational demands and job characteristics across occupations led to a general endorsement of the concept of situational specificity, whereby there was no expectation that personality predictors could maintain comparable validity across occupations (Schmidt & Hunter, 1977). This was compounded by a broader literature stating that characteristics of a situation were strong enough to influence behavior to the degree that stable individual traits, if there were any (Davis-Blake & Pfeffer, 1989), had little effect on an individual's behavior (Mischel, 1968).

This situation led to two important events for researchers wanting to apply personality concepts in employment settings. First was a call to focus on the taxonomic structure of the personality domain at the expense of developing additional measures (Dunnette, 1962 [cited in Guion & Gottier, 1965]). A scientific framework was needed to describe the domain of personality characteristics, and further to describe how these characteristics were supposed to relate to individual work behavior. Although it was possible to use many hundreds of terms to describe a person's attributes in the personality domain, it was counterproductive not to combine like terms and develop a parsimonious taxonomy. It was around this time that personality researchers began the studies that ultimately led to the Five Factor Model described above. The development of a usable taxonomy of personality characteristics was crucial; it provided the framework upon

which research results could be meaningfully cumulated (e.g. Barrick & Mount, 1991; Hertz & Donovan, 2000).

The second development was, to some degree, a consequence of the first. While personality psychologists devoted substantial research effort to studying the internal structure of personality, they often did so at the exclusion of studying external correlates. That is, more attention was directed at understanding relationships among personality measures than understanding whether and how personality could predict other variables of interest (Hogan, 2006). Thus, attention needed to be focused on external variables in the nomological networks of personality characteristics (Cronbach & Meehl, 1955) – what did these characteristics meaningfully relate to, and thus, what criteria could be predicted? The calls for research into the structure of personality and careful examination of its correlates ultimately led to a general acceptance of personality predictors by I-O psychologists, described next.

Mixed Feelings About the Utility of Personality Predictors in the Workplace

In a series of integrative reviews, Hough and her colleagues (Hough & Dilchert, 2010; Hough & Furnham, 2003; Hough & Oswald, 2008) attribute renewed interest in personality variables among I-O psychologists to the two major and broad developments just noted: a) evidence that individuals' scores on personality assessments predicts valued job performance, and b) further development of a taxonomic structure of human personality that forms a common language for theories about why personality ought to be relevant for job performance. These developments have formed the basis for large-scale research to support the use of personality assessment.

Three landmark meta-analyses are credited for presenting empirical evidence for the utility of occupational personality assessments. Hough, Eaton, Dunnette, Kamp, and McCloy (1990) cumulated criterion-related validity information for personality constructs as part of a literature review for the U.S. Army's Selection and Classification Project, widely known as Project A. Hough et al.'s initial purpose was to identify personality and temperament constructs that could be useful in predicting job-related criteria. Hough et al. went to great lengths to organize the personality and temperament measures into construct categories that were at least somewhat discrete. They ended up with seven categories: surgency, adjustment, agreeableness, dependability, intellectance, affiliation, and miscellaneous. Average correlations among measures within each of the six substantive categories (that is, not including miscellaneous) ranged from .33 (affiliation) to .46 (surgency). Average cross-category correlations were all of lower magnitude than average within-category correlations. The average correlation for the miscellaneous category was .05. Hough et al. interpreted this as possible evidence for why previous investigations (Guion & Gottier, 1965; Schmitt, Gooding, Noe, & Kirsch, 1984) yielded little evidence for the predictive validity of personality measures: These studies were thought to combine measures of disparate constructs, thus obscuring their nomological network. Hough et al. went on to report a range of criterion-related validities across the personality categories and various criteria. Notably, personality predictors showed lower correlations with task-focused criteria (job proficiency) and higher correlations with non-task criteria (delinquency). The patterns of validities also formed the basis for Schneider, Hough, and Dunnette's (1996) subsequent critique of the Big Five factors as obscuring

important differences among personality variables that are not aggregated to the Big Five taxonomic level.

While Hough et al. (1990) made major advancements by categorizing personality scales into a meaningful taxonomy, Barrick and Mount (1991) and Tett, Jackson, and Rothstein (1991) expanded on that concept by grouping measures according to their correspondence with the Big Five framework noted above. These two studies used somewhat different procedures for conducting meta-analyses, and thereby yielded different results in terms of validity coefficient magnitudes, but both are credited for providing large-scale evidence that personality assessments can predict job performance ratings. In particular, Barrick and Mount (1991) showed that the validity of conscientiousness could be expected to be non-zero across all of the studies and occupations they examined. The variance in criterion-related validities for conscientiousness, as well as for agreeableness, emotional stability, openness, and extraversion suggested the importance of moderators, or study characteristics that condition the relationships among personality measures and criteria. Examples of these moderators included occupation types or criteria of interest. In addition, Tett et al. provided evidence that specific personality characteristics tended to exhibit larger correlations with criteria in situations in which there were theoretical reasons for the link, as reflected in job analysis data.

Building on the work of Barrick and Mount (1991), Hough et al. (1990), and Tett et al. (1991) researchers have undertaken efforts to understand the moderating effects of study characteristics moderating personality—performance relationships. Simply in terms

of the accumulation of personality-related effect sizes across studies, the literature now contains meta-analyses of Big Five factor predictive validity when scales were designed to measure the Big Five specifically (Hurtz & Donovan, 2000), personality ratings were made by observers (Connelly & Ones, 2010; Mount, Barrick, & Strauss, 1994; Oh, Wang, & Mount, 2011), in jobs requiring interpersonal interactions (Mount, Barrick, & Stewart, 1998), sales jobs (Vinchur, Schippman, Switzer, & Roth, 1998), when leadership effectiveness is of interest (Judge, Bono et al., 2002), when only single personality measures are used to bypass issues with combining different tests (Bartram, 2005; Hogan & Holland, 2003), when predictors are rationally and theoretically linked to specific criteria (Hogan & Holland, 2003), when counterproductive behavior (CWB) is the criterion of interest (Berry, Ones, & Sackett, 2007; Salgado, 2002), when organizational citizenship behavior (OCB) is the criterion of interest (Chiaburu, Oh, Berry, Li, & Gardner, 2011), and when academic performance is the criterion of interest (Poropat, 2009). This is not an exhaustive list (note that other meta-analyses containing some, but not all, of the Big Five are not included in this list), but it is intended to represent the range of investigations that have been reported. In all cases, the authors of these studies concluded that the Big Five or its components are relevant predictors of various criteria of interest. In lieu of reporting specific validity coefficients from these studies here, note that large summary tables appear in Barrick, Mount, and Judge (2001), Hough and Furnham (2003), and Ones, Dilchert, Viswesvaran, and Judge (2007).

In spite of the optimism generated by these studies, there remains controversy in the academic literature over the use of personality in making personnel decisions with

tangible employment consequences. In some cases, this has resulted in hesitation by practitioners about using personality predictors in applied settings. Criticisms of personality assessments, most recently outlined by Murphy and Dzieweczynski (2005) and Morgeson et al. (2007), include the following issues:

- (a) Bivariate validity coefficients are too small. While intuition suggests that aspects of an individual's personality ought to be strongly related to how he or she behaves when working, many criterion-related validity coefficients do not meet a magnitude threshold to be deemed important. A sampling of the magnitudes of meta-analytic correlations between personality predictors and job performance criteria is drawn from work by Sackett and Walmsley (2012) and is shown in Appendix A.
- (b) Job applicants can and do intentionally misrepresent themselves to appear well fit for the job. This process, termed by many as faking, results in a lack of information about an applicant's true tendencies. Additionally, those who fake on a personality test may displace truthful and deserving applicants by falsely appearing to be better qualified for employment.
- (c) Personality measures often are not chosen based on a job analysis, and thus may or may not provide relevant information on which to base employment decisions.
- (d) Theories linking personality to occupational performance are weak and lack detail about the functional form of the relationship.

- (e) Personality measures do not “behave” psychometrically the same way that cognitive ability measures do. That is, personality measures do not display strong positive manifold, even when separate measures are ostensibly designed to tap the same constructs. This is also related to the criticism outlined in (a) above. That is, in addition to low magnitude validity coefficients, meta-analytic moderator analyses (including credibility intervals and homogeneity tests) suggest that the bivariate validity for most, if not all, personality predictors can be zero in some situations and thereby are not generalizable.
- (f) There are likely occupational characteristics that moderate the functional form of personality—performance relationships, and as a science, we do not understand these characteristics or their effects very well.

These issues are complex and the goal of this dissertation is not to directly respond to all of them. Replies to Murphy and Dzieweczynski (2005) and Morgeson et al. (2007) were published by Ones et al. (2005), Hogan (2005), Barrick and Mount (2005), Ones et al. (2007), and Tett and Christiansen (2007). However, these replies are only able to focus on some of the issues listed above, and none provided evidence on issues of possible nonlinearity. Some of the disagreements are likely rooted in differing value judgments that are likely intractable among researchers. Other responses to criticisms levied by Murphy and Dziweczynski and Morgeson et al. simply require further research.

Questions of Interest in the Current Study

This dissertation focuses on contributing to the literature by addressing at least some of the parts of this ongoing controversy. Specifically, the questions raised above about (a) validity, (d) theory and evidence on the personality—performance functional form, and (f) occupation-level moderators, are of interest here.

Recognizing that the bivariate validity coefficients for personality predicting overall job performance are relatively low in magnitude when compared to coefficients for cognitive ability tests or measures of job-related knowledge, skills, and abilities (Schmidt & Hunter, 1998), researchers have suggested a number of measurement and statistical approaches for enhancing criterion-related validity. Examples include contextualizing personality items (i.e. adding “at work” to an otherwise non-occupationally-focused personality item; Heggstad & Gordon, 2008; Schmit, Ryan, Stierwalt, & Powell, 1995), gathering observer ratings of personality to predict job performance (Connelly & Ones, 2010; Oh et al., 2011), using forced-choice formats (Baron, 1996; Heggstad, Morrison, Reeve, & McCloy, 2006; Jackson, Wroblewski, & Ashton, 2000), using conditional reasoning as a subtle measure of personality (James, 1998), and conducting multivariate analyses (Ones et al., 2007), as the classical bivariate model appears to have caused a lot of consternation (Campbell, 1990). Hough and Dilchert (2010) recently reviewed these approaches and concluded that they have increased our understanding of strategies that appear useful in validation work.

This study takes a different tack. The focus here is on investigating the functional form of the personality—performance relationship throughout the range of scores on both personality and performance variables. Almost all correlational studies of personality’s

links to job performance appear to have implicitly carried the assumption that the best fitting summary is linear. Thus, when each Big Five factor is scaled on a continuum where lower scores reflect lower trait desirability, lower scorers are likely to perform worse relative to higher scores, and this relationship remains linearly monotonic throughout the personality and performance score ranges. This could be characterized as “more is better”. In contrast, a nonlinear relationship suggests several alternatives:

- (a) Possibility one is a negative quadratic relationship, whereby those in the middle of the personality score range tend to have higher performance scores than those low or high in the personality range. This possibility could be characterized as “inverted-U-shaped” and would indicate that personality scores less than the highest scores would provide the optimal forecast for performance.
- (b) Possibility two is a positive quadratic relationship, whereby those in the low and high personality score ranges would tend to have higher performance scores than those in the middle of the personality score range. This possibility could be characterized as “U-shaped” and would indicate that personality scores near the high and low ends of the range are associated with optimal performance.
- (c) Possibility three is a decelerating positive relationship that flattens above a particular personality score. This type of relationship would be consistent with the “good enough” hypothesis often posited for the relationship between cognitive ability and performance (Arneson, Sackett, & Beatty, 2011).

Asymptotic relationships between personality and performance would indicate that it is beneficial to score increasingly high on a given personality trait up to a certain point on the scale. Above that threshold, however, personality scores would not be useful for forecasting which applicants may be better performers.

These three possibilities guide the research question development in this study. Note that these are not the only possibilities for the relationship between two variables (e.g., cubic functions), but represent the most likely possibilities for the personality—performance functional form (Hough & Dilchert, 2010).

The possibilities outlined above are not new ideas; researchers have explicitly suggested the possibility of nonlinear relationships with occupational criteria since at least Murphy (1996). Unfortunately, studies of nonlinear relationships require unusually large samples and somewhat sophisticated analyses (Cohen et al., 2003), and only a few such studies have been reported. The next section describes research to date on the personality—job performance functional form, and is organized by each Big Five factor. For each factor, theoretical reasons for nonlinear forms are suggested, followed by a review of the evidence to date.

Theory and Evidence On Nonlinear Personality-Job Performance Relationships

Conscientiousness—Job Performance Theory. Consistent with adjectives used in the I-O literature (Barrick, Mount, & Judge, 2001), Goldberg (1992) reported a study of personality markers in which low conscientiousness was described as “disorganized”, “careless”, “inefficient”, “undependable”, and “haphazard”, whereas high

conscientiousness was described as being “organized”, “systematic”, “thorough”, and “efficient”. Those scoring high on conscientiousness scales are typically said to be dependable, persevering, careful, and self-disciplined (Barrick et al., 2001; Goldberg, 1992). If these characteristics are important for job performance, and low scorers tend to be disorganized, impulsive, or undependable, then it is reasonable to expect that low scorers on conscientiousness scales will underperform relative to higher scorers, on average. Consistent with this expectation, previous meta-analytic correlations suggest a small positive relationship between conscientiousness and various indices of performance such as overall job performance (Barrick & Mount, 1991), task performance (Hurtz & Donovan, 2000), organizational citizenship behavior (OCB; Hurtz & Donovan, 2000), and avoidance of counterproductive behavior (CWB; Berry, Ones, & Sackett, 2007; Salgado, 2002). However, some scholars have suggested that there may be a point in the conscientiousness score range at which higher levels of the trait do not contribute to better performance or become detrimental to performance.

Considering the high range of scores, Murphy (1996) suggested that individuals high on conscientiousness may be “... so conventional and rule-bound that [they] cannot function in anything but the most bureaucratic setting” (p. 22). Murphy and Dzieweczynski (2005) proposed that managers very high on conscientiousness might not have a realistic sense of when it is better to go “by the book” versus show flexibility in application of rules and regulations. Similarly, Le et al. (2011) argued that high-conscientiousness individuals tend to get bogged down into details such that they may overlook important goals or miss critical information. Le et al. also noted a study by

LePine, Colquitt, and Erez (2000), in which participants working under a time limit were required to incorporate new knowledge and skill as the task characteristics changed.

Participants scoring high on the dependability facet of conscientiousness had more difficulty with this adaptation than those scoring lower, presumably because they focused too heavily on a task performance goal at the exclusion of acquiring and applying new knowledge.

MacLane and Walmsley (2010) argued that recent clinical psychology literature also provides a basis from which to draw inferences about optimal levels of conscientiousness for work performance. Current work on the American Psychiatric Association's *Diagnostic and Statistical Manual* is moving towards incorporation of dimensional models of personality for diagnosis and classification of personality disorders. This is a stark contrast with previous categorical schemes (Widiger & Trull, 2007). The primary dimensional models under consideration are the Big Five model and very similar variants (Krueger, Eaton, Clark, Watson, Markon, Derringer, Skodol, & Livesley, 2011; Miller, Bagby, & Pilkonis, 2005; Walton, Roberts, Krueger, Blonigen, & Hicks, 2008). It is critical to note that any test that is diagnostic of a medical condition, such as a personality disorder, is impermissible for initial employment decisions under the Americans with Disabilities Act. However, the work done by clinical and personality psychologists in describing the full range of personality characteristics, particularly the extremely high ends of the trait continuum, can be useful for theory development for each of the Big Five. In addition, these characteristics may foreshadow problematic tendencies

at high ends of the normal range. For instance, Widiger, Costa, and McCrae (2002) describe those high in conscientiousness as follows:

Overachievers; shows workaholic absorption in his or her job or cause to the exclusion of family, social, and personal interests; is compulsive, including excessively clean, tidy, and attentiv[e] to detail; has rigid self-discipline and an inability to set tasks aside and relax; lacks spontaneity; is overscrupulous in moral behavior. (p. 442)

Widiger et al. go on to provide descriptions of high and low poles of six facets of conscientiousness, corresponding to the NEO Personality Inventory (NEO-PI; Costa & McCrae, 1992). As the Big Five represent the level of abstraction of typically of most interest in employment settings (Hurtz & Donovan, 2000; cf. Ones & Viswesvaran, 1996), the focus here is not on the facets, but rather their contribution to a conscientiousness-level understanding or bandwidth.

The implications suggested for high levels of conscientiousness from the non-clinical and clinical literatures converge on several important points: First, relevant to the performance of work tasks, it appears possible that those above a certain point on conscientiousness may display debilitating perfectionism, may exhibit rigidity about rules and their concepts of order, and excessively ruminate over decisions. Second, these characteristics may prevent highly conscientious individuals from completing tasks and making decisions in a timely manner, acquiring beneficial knowledge, or recognizing opportunities to display flexibility in applying new skills. Third, as low-conscientiousness descriptors tend to include low self-discipline, carelessness about rules and consequences

of decisions, and general undependability, it is expected that low, moderate, and some high conscientiousness scores will be related positively to job performance. Fourth, the point at which conscientiousness may be optimally associated with performance, and then turn to a negative slope, is unknown and may be at such extremely high scores that they occur rarely in normal populations. This fourth point raises the additional question of the degree to which the location of an inflection point or nonlinear turning point is measure dependent. From a scientific perspective, the turning point of interest refers to the level of the personality *construct* (or theta level) at which nonlinearity occurs. However, given differences in various personality measures' sensitivity to the range of the underlying construct, any point of inflection may be within the possible scale on some inventories while off the scale on others.

Conscientiousness—Job Performance Evidence. Evidence for nonlinear conscientiousness—performance relationships in employment settings is mixed. Robie and Ryan (1999) tested for curvilinearity using conscientiousness scores from administrations of the NEO-PI-R in Federal Government (n = 999) and private sector (n = 200) settings. They also examined conscientiousness scores from the Personal Characteristics Inventory (PCI) in three samples: DoD managers (n = 146), wholesale sales reps (n = 206), and long-haul semi truck drivers (n = 256). The criterion variable was supervisory ratings of overall job performance for all samples. Using the generally accepted hierarchical polynomial regression analyses within each sample, Robie and Ryan (1999) found no evidence for curvilinearity in conscientiousness—performance relationships.

LaHuis, Martin, and Avis (2005) also tested for nonlinearity using two different personality assessments. The first assessment was comprised of 17 situational judgment and biodata items. Situational judgment items consisted of a scenario, several response options, and instructions to respondents to choose the response that represents what they would do. Biodata items were asked about previous work experiences related to conscientiousness, such as preparation to complete tasks. The items were administered to 192 entry-level clerical employees at a federal agency. The second assessment was the conscientiousness subscale from the NEO, administered to 203 clerical employees at a state government agency. The criterion measure for both samples was a single-item research focused supervisory judgment of overall job performance. In their first sample, LaHuis et al. found a significant negative quadratic effect for conscientiousness—performance, such that the relationship started positive, leveled off, and became slightly negative at the high end of the conscientiousness score range. In sample two, LaHuis et al. found a decelerating positive relationship that represented an asymptote at high levels of conscientiousness.

Cucina and Vasilopoulos (2005) examined the form of conscientiousness—freshman college grade point average (FGPA) relationships among 262 undergraduate students. They used the 100-item Big 5 measure from the International Personality Item Pool (IPIP; 20 items are designed to assess conscientiousness). They found a negative quadratic relationship in the form of an inverted-U. Vasilopoulos, Cucina, and Hunter (2007) reported similar findings for another academically-oriented criterion: training performance. Vasilopoulos et al. found a negative quadratic relationship between a

locally-developed conscientiousness measure and performance on indices of classroom learning (topics such as laws and operations content) at the Federal Law Enforcement Training Center (FLETC). The personality assessment showed adequate convergent validity with the NEO and had an internal structure consistent with other Big Five measures. Of note, Vasilopoulos et al. probed the available conscientiousness facets for the quadratic effect, finding the effect for dependability but not achievement.

Whetzel, McDaniel, Yost, and Kim (2010) reported a negative quadratic relationship between conscientiousness, which was 1 of 32 scales measured using SHL's ipsative Occupational Personality Questionnaire (OPQi), and a task performance rating composite based on a 15-item scale developed for research purposes. Their sample consisted of 1,152 professionals in a financial services firm, and was split into equal halves for cross-validation. When the quadratic term was added to their regression model to test for nonlinearity, the change in R^2 was approximately .05, which they interpreted as minimal evidence for nonlinearity. Whetzel et al. suggested that the addition of a quadratic or cubic term must change increment R^2 at least .05 to be meaningful. However, this rule-of-thumb was not applied in other studies and thereby may have lead Whetzel et al. to draw somewhat different conclusions than other investigators. Additionally, Whetzel et al. divided their sample in half and required the R^2 increment to meet the .05 threshold in both samples to be considered evidence for nonlinearity.

In arguably the most comprehensive study to date, Le et al. (2011) reported negative quadratic nonlinear relationships between conscientiousness and three distinct criteria in a sample of 602 participants from a concurrent validation study in a public

organization. The three criteria assessed were task performance, citizenship behavior, and counterproductive behavior, all based on supervisory ratings collected for research purposes. Conscientiousness was assessed using a locally-developed construct-based integrity test that included several other personality constructs and overt integrity items. Yet, Le et al. were unable to replicate these findings using another sample and a different personality assessment. Their second study was also conducted in a concurrent validation framework, and involved 956 participants from 25 organizations. As with their first study, their criteria included supervisory ratings of task, citizenship, and counterproductive performance. In this study, the personality test was a Big 5 questionnaire developed by ACT: the WorkKeys Talent Assessment. For each criterion, Le et al. found no evidence of non-linear relationships with the conscientiousness predictor.

To summarize, the current I-O psychology literature contains several published studies investigating nonlinear relationships between conscientiousness and a variety of performance indices, and results have been mixed. It is difficult to pinpoint contributing factors for the range in findings; it may be that sample sizes, sample characteristics, measurement instruments, criterion variables, or other moderating conditions all contribute to the lack of clear findings.

Research Question 1: Is the relationship between conscientiousness and performance best described as a linear or quadratic function?

Agreeableness—Job Performance Theory. Little theory exists regarding whether to expect nonlinear agreeableness—performance relationships, but the concept

resonates intuitively. Given that much work is accomplished in a social environment, disagreeableness can generally be regarded as unadaptive. Goldberg's (1992) study of Big Five markers yielded low agreeableness descriptors such as "cold", "unkind", "distrustful", "harsh", and "rude", whereas high agreeableness was described as being "kind", "cooperative", "warm", "trustful", and "considerate". The key question for nonlinearity is whether the high end of these traits can be maladaptive. Murphy and Dzieweczynski (2005) suggested that highly agreeable managers may fail to deliver bad news or critical feedback that would be helpful to employees. Extrapolating to non-managers, highly agreeable people may not advocate for their opinions, express healthy dissent, or negotiate well in the workplace. This may be due to a tendency to want to please others.

Drawing on the clinical literature, Widiger et al. (2002) outline possible characteristics of highly agreeable people; these tendencies may lead them to face issues in the workplace:

[They are] gullible; shows indiscriminant trust of others; shows excessive candor and generosity to the detriment of self-interest; has an inability to stand up to others and fight back; easily taken advantage of. (p. 441)

Thus there are several possibilities for reasons why those scoring very high in agreeableness may not perform as well as those scoring somewhat lower. In terms of task performance, highly agreeable people may take on excessive workloads due to an inability to turn down requests from others. This could lead to failure to meet goals adequately. In team settings, they may withhold opinions and suggestions in an attempt to

avoid offending others. Similarly, they may be taken advantage of by team members or customers, which may lead highly agreeable people to sacrifice their goals or the goals of their team, or exceed budgets in a customer service environment. These reasons are consistent with meta-analytic findings that agreeableness does not meaningfully predict performance in sales positions, as there may be a relationship between low levels of agreeableness and performance, but nonlinearity in the high score range may weaken any linear effect (Barrick & Mount, 1991; Vinchur, Schippman, Switzer, & Roth, 1998). It is difficult to conceptualize high agreeableness as a detriment to organizational citizenship behavior (OCB), beyond the possibility that OCB may come at the expense of task performance if a performance episode is a zero-sum game. It also may be unlikely that highly agreeable people will intentionally engage in counterproductive behavior towards others. However, the possibility remains that highly agreeable people could engage in behavior counter to an organization's legitimate interests in negotiations, especially if agreeable people fail to negotiate the best possible circumstances for the organization they represent.

Agreeableness—Job Performance Evidence. To date, there are virtually no reported investigations of nonlinear agreeableness—performance relationships based on Big Five-oriented scales. Thus one goal of this study is to provide the first major tests in this domain. However, one could speculate that analyses may have been conducted but not reported. For instance, Le et al. (2011) report using an integrity test partially intended to measure agreeableness in their first study, and used a Big Five assessment, presumably including agreeableness, in their second study. Perhaps they were unable examine the

agreeableness portion of their measure, or have the space allotted to report what some may consider as an uninteresting or null finding. While this is heavily speculative, the argument here is that knowing that nonlinearity analyses were conducted and came up unsupportive is as important as finding evidence of nonlinearity.

Whetzel et al. (2010) included some agreeableness-related scales in their study using the OPQi. Examples include ipsative scales designed to measure the degree to which people are *Caring* and *Trusting*. In both cases, analyses revealed no evidence for nonlinearity in the prediction of rated task performance. Finally, Cucina and Vasilopoulos (2005) reported tests of curvilinear relationships between IPIP Agreeableness and first semester college GPA, finding no evidence for nonlinearity.

Research Question 2: Is the relationship between agreeableness and performance best described as a linear or quadratic function?

Emotional Stability—Job Performance Theory. Based on Goldberg’s (1992) work, those who score low on emotional stability scales may be described as “anxious”, “moody”, “temperamental”, “fretful”, and “jealous”, while those scoring high could be said to be “relaxed”, “unenvious”, “unemotional”, and “unexcitable”. Drawing from the Yerkes-Dodson law, which specifies that potentially optimal levels of arousal lie in the middle of the range, Vasilopoulos et al. (2007) suggested that, past a certain point on the emotional stability score range, increased scores may be unlikely to contribute to performance on moderately difficult tasks such as the training performance indices they examined. Although they did not directly address social situations, it is possible that very high scorers on emotional stability may be viewed by others as unresponsive to problems

or uninterested in their viewpoints on issues. The argument is that there is an optimal level of emotional arousal that allows one to complete work tasks and interact productively with others, and this optimal level does not lie in the very high end of the emotional stability score range. Essentially, there may be a “good enough” level of emotional stability; beyond this level there is no additional advantage in terms of contribution to job performance (Le et al., 2011).

While emotional stability may be related asymptotically to performance of the technical core of the work, it may bear relationships of a different functional form with CWB. Le et al. (2011) suggested that emotional stability (ES) influences how one reacts to a variety of job stressors, and that the optimal degree of ES depends on the stressors. Accordingly, they suggested a negative relationship that asymptotes at higher levels of ES, such that low ES is associated with greater CWB than moderate ES, whereas high ES provides no further decrement in CWB. Thus the functional form may be said to be U-shaped, or possibly somewhat L-shaped.

Widiger et al. (2002) offered the following description of high ES on the basis of the clinical and personality literatures: “Lacks appropriate concern for potential problems in health or social adjustment; shows emotional blandness” (p. 438). Thus the primary implication of high ES for decrements in job performance may be in occupations or situations in which display of heightened arousal or problem sensitivity is optimal.

Emotional Stability—Job Performance Evidence. Two reports of examinations of ES—performance exist in the literature. The first was from Vasilopoulos et al. (2007), who examined scores on a measure of ES, as well as its stress resistance and frustration

tolerance components, in relation to training performance in a sample of 1,010 federal law enforcement trainees. Vasilopoulos et al. found evidence for a negative quadratic (inverted-U) relationship, consistent with mid-range standing on ES being optimal for training performance. They also reported that the negative quadratic was found for the stress resistance facet, but not for the frustration tolerance facet. It is possible that the training environment from which criterion data were drawn did not present adequate stimulus for the full range of frustration tolerance to be displayed. Following this study, Whetzel et al. (2010) examined OPQ scales for *Emotionally Controlled* and *Worrying*, and reported no evidence for nonlinearity.

Le et al. (2011) examined two separate measures of ES in two samples. Study 1 involved 602 incumbents in a public organization who completed a construct-based integrity test and were rated by their supervisors on several dimensions of performance. The ES component exhibited a negative quadratic relationship with ratings of task performance and ratings of OCB. In contrast, Le et al. reported a positive quadratic (U-shaped) form for the ES—CWB relationship. Study 2 involved a very similar design, in which 956 participants completed the WorkKeys Talent Assessment Big Five measure. In this sample, Le et al. found no evidence of curvilinearity for task performance, a negative quadratic for ES—OCB, and a positive quadratic for ES—CWB. Thus the results for OCB and CWB criteria were replicated, but the task performance results did not replicate.

Research Question 3: Is the relationship between emotional stability and performance best described as a linear or quadratic function?

Openness to Experience—Job Performance Theory. According to Goldberg (1992), people scoring low on openness are described as “unintellectual”, “unimaginative”, “uncreative”, and “simple”, whereas those high on openness are labeled “intellectual”, “creative”, “complex”, “bright”, and “philosophical”. There is little developed theory relevant to whether high openness scores may have nonlinear implications for job performance. As with other domains, examination of clinical psychology literature may provide insight. Widiger et al. (2002) describe high openness as:

Is preoccupied with fantasy and daydreaming; lacks practicality; has eccentric thinking (e.g., belief in ghosts, reincarnation, UFOs); has a diffuse identity and unstable goals, for example, joining a religious cult; is susceptible to nightmares and states of altered consciousness; shows social rebelliousness and nonconformity that can interfere with social or vocational advancement. (p. 440)

While some of these implications clearly fall outside the domain of work, some are relevant to the workplace, such as lacking practicality or exhibiting rebelliousness or nonconformity with consequences for vocational advancement. For example, creative problem solving is often espoused as a critical skill for successful performance in many occupations (Mumford, Peterson, & Childs, 1999; Reiter-Palmon, Mumford, & Threlfall, 1998). In most cases, creative solutions to workplace problems are optimal to the extent that they are useful within the circumstances of the issue. Thus, while openness is likely a useful personal characteristic for identifying creative solutions, high openness may be detrimental if suggestions lack practicality.

If high openness can lead to generation of many ideas for solving work problems, an additional implication for nonlinearity is constantly changing goals. If being open to trying many courses of action results in one's inability to choose and stick with a plan, this may be detrimental for task performance in the high range of openness. As with other Big Five personality characteristics, the key question is whether detrimental levels of openness are observed in the workplace, beyond being possible from a theoretical perspective.

Openness to Experience—Job Performance Evidence. Only one study has assessed openness within the Big Five framework and tested for the presence of nonlinear relationships. Cucina and Vasilopoulos (2005) used the IPIP 100-item Big Five measure to assess openness for 262 undergraduate students and examined the form of its relationship with first semester GPA. They found evidence for a positive quadratic (U-shaped) relationship, whereby optimal levels of openness for FGPA were in the high and low ends of the score range. Thus, although their study was in academic setting, Cucina and Vasilopoulos provided evidence that openness can exhibit curvilinearity when compared to performance in a consequential domain.

Within the occupational domain, Whetzel et al. (2010) reported some openness-related scales in their study using the OPQi. While direct Big Five links are not available, examples of these scales included measures of the degree to which people are *Adaptable*, *Innovative*, *Conventional*, *Forward Thinking*, and *Variety Seeking*. Using their R^2 increment of .05 in both split-half samples as a rule-of-thumb, Whetzel et al. reported no evidence for curvilinearity between these measures and ratings of job performance. As

expected, if the .05 criterion was relaxed to .01, some of the findings can be interpreted as evidence for nonlinearity. Additionally, some researchers in other studies relied on statistical significance as evidence for the meaningfulness of polynomial regression terms, whereas Whetzel et al. emphasized effect size. Although both approaches may have merit, this makes direct comparisons among studies difficult.

Research Question 4: Is the relationship between openness and performance best described as a linear or quadratic function?

Extraversion—Job Performance Theory. Goldberg (1992) offered the following descriptors for low extraversion (labeled *Surgency*): “shy”, “quiet”, “reserved”, “inhibited”, and “withdrawn”. Conversely, adjectives for high extraversion included “talkative”, “assertive”, “energetic”, “bold”, “daring”, and “unrestrained”. Murphy (1996) provides an example for why extraversion may exhibit a negative quadratic (inverted-U) relationship with team performance: those scoring lower may experience discomfort in team interactions and thereby may not participate or otherwise work well with others, whereas those scoring high might spend all their time socializing at the expense of completing tasks. This could be an important issue given that many work tasks are completed in interdependent teams (cf., Bell, 2007). From the clinical perspective, Widiger et al. (2002) describe high extraversion as:

Talks excessively, leading to inappropriate self-disclosure and social friction; has an inability to spend time alone; is attention seeking; shows overly dramatic expressions of emotions; shows reckless excitement seeking; inappropriately attempts to dominate and control others. (p. 439)

Thus high extraversion could exhibit nonlinear relationships in interpersonal performance settings, building on Murphy's (1996) suggestions. Additionally, while extraversion is related to leader emergence (Judge, Bono et al., 2002), this may come at the price of others feeling as though they have been stepped by on an extremely dominant individual. This has similar implications for CWB, as any attempts to control others in the workplace could be interpreted as Machiavellianism (Kessler, Bandelli, Spector, Borman, Nelson, & Penney, 2010).

Extraversion—Job Performance Evidence. There are no studies examining nonlinear functional forms between Big Five measures of extraversion and occupational performance. However, Whetzel et al. (2010) include some scales potentially relevant as facets of extraversion in their investigation, namely, *Affiliative*, *Outgoing*, *Outspoken*, and *Socially Confident*. Under their R^2 increment of .05 in both samples rule-of-thumb, none of these scales showed curvilinear relationships with job performance. Cucina and Vasilopoulos (2005) report polynomial regression results for IPIP-Extraversion using a first-semester GPA criterion for college students. They reported an R^2 change of .000 and a non-significant regression weight when the polynomial term was entered.

Research Question 5: Is the relationship between extraversion and performance best described as a linear or quadratic function?

Finally, two studies by Benson and Campbell (2007) are of note. These researchers investigated the possibility that personality-based characteristics thought to relate to leadership derailment were related in a nonlinear fashion to indices of leadership behavior. The derailing composites examined by Benson and Campbell were composed

of several personality scales that represented very high or very low standing on Big Five traits. In their first study, examples of these characteristics included leaders' propensity to be ego-centered, manipulative, micro-managing, or passive-aggressive. In their second study, examples of these characteristics included excitability, skepticism, being overly cautious, bold, or mischievous. Benson and Campbell reported significant negative quadratic effects for composites of these personality predictors in relation to several indices of leader behavior across two samples.

Summary of Issues Related to the Inferences From Previous Studies

There are a number of reasons why the studies reviewed above have not provided definitive conclusions about the nonlinearity question, with several scholars noting that the state of the literature is still inconsistent (Converse & Oswald, 2012; Schmidt, 2010). The most obvious reason is the presence of conflicting findings, going beyond issues with presence or absence of statistical significance that often cloud narrative reviews. This is particularly evident in domains with the most studies; namely, the conscientiousness domain. Conflicting findings are, in and of themselves, not necessarily a satisfying motivator for additional research, as they may be symptomatic of many potential issues. In particular, studies in applied psychology generally, and nonlinearity more specifically, make use of convenience samples, which may be representative of a limited population. This may be the case due to preselection on a complex set of known and unknown factors. Additionally, both Hough and Dilchert (2010) and the Society for Industrial and Organizational Psychology's *Principles for the Validation and Use of Personnel Selection Procedures* (SIOP, 2003, p. 21) describe the necessity for very large samples in

attempts to detect nonlinearity. Thus it is possible that sampling error and a lack of power have played critical roles in the cumulative record of previous research. A related concern is the question of whether observed personality scale scores covered enough of a range to detect nonlinearity – particularly extremely high scorers. It is unclear whether scorers covering the full range of responses were present in previous studies. Sampling from the high-scoring end of the predictor distribution is particularly important in studies of this nature (Little, 2007). Adding to differences in interpretations across studies, Whetzel et al. (2010) suggested R^2 -change rules of thumb that were not similarly applied in other studies, some of which appear to have relied more on statistical significance than effect size.

A variety of criterion measures (e.g., supervisor ratings of overall performance, GPA, training performance, counterproductive behavior) were used in the previous studies, some perhaps more comparable than others. These criteria may be unaligned with certain predictors; an example is that performance on knowledge acquisition measures in a training context may be likely to demonstrate small relationships with personality measures. Additionally, various personality measures were employed as predictors across the studies. Construct validity is a particular concern, as Hough et al. (1990) reported often low mean correlations among personality measures of common conceptual domains. As an example, while many scales measuring “conscientiousness” exist, they often differentially emphasize various facets such as achievement orientation, orderliness, dutifulness, or self-discipline. Beyond construct coverage, measurement properties differed among at least some of the measures. For instance, the ipsative measure studied

by Whetzel et al. (2010) may yield different scale information than non-ipsative forms of similar assessments.

Finally, there has been little discussion of implications for applied measurement situations, in which decisions carrying tangible employment consequences are made about those completing personality measures. Hough and Dilchert (2010) noted that the presence of curvilinearity could dictate whether certain uses of personality scores make more sense than others, such as top-down selection strategies, setting cut scores for screening purposes, or methods for combining personality scores with other assessment information. Converse and Oswald (2012) presented a simulation documenting potential losses in performance if personality data are treated as linear when the relationships are truly nonlinear. Thus, in spite of compelling rationale for nonlinear relationships, it is necessary to understand whether and when these effects occur (Grant & Schwartz, 2011). The follow-on question is whether nonlinearity matters in operational settings. The most immediate implications would be for two situations: First is a setting in which a cut score is identified in the predictor distribution and candidates are rejected below the score. In the presence of a substantial negative quadratic curvilinear effect, it would be possible for some candidates who pass the cut score to perform worse than those rejected. Second is a setting in which rank-ordered top-down selection decisions are made on the basis of personality predictors. In this condition, the most serious issues would occur when a negative slope describes the personality—performance relationship in the high score range. This problem would be minimized in the case of asymptotic nonlinearity (Hough & Dilchert, 2010). In both cases, a critical issue is the point in the personality score range

in which the validity coefficient describes a negative relationship (if at all). Theoretically, it is important to understand possible nonlinear relationships, but the practical problems would be minimized if the point at which validity becomes negative occurs outside of either (a) the typical observed score range or (b) the possible score range. Building on the above discussion about the possible differences in measurement properties between specific assessments, it is also the case that personality inventories may differ in whether a nonlinear turning point occurs within or beyond the observed scale range.

In addition to the factors noted here, conflicting findings among studies suggest the importance of moderating variables, which are explored more fully in the next section.

Possible Moderators of Personality—Job Performance Functional Forms

One way to summarize the review above is to note that the current I-O psychology literature contains approximately six published studies of nonlinearity of conscientiousness, two studies of emotional stability, one study of openness, and no studies of agreeableness and extraversion. This statement is predicated on the use of assessment instruments that are designed to measure each personality characteristic at the definitional level of abstraction of the five-factor model. While these studies have shed light on the possibility of nonlinear personality—performance relationships, the mixed results across studies suggests at least two possibilities, namely, (a) sampling error or (b) the presence of moderating variables. Differences in results due to sampling error are possible in any similar set of studies. In this case, sample idiosyncrasies or capitalization on chance characteristics of the samples studied could have yielded differences in

findings across studies. Johnson and Hezlett (2008) argue that sampling error cannot account for all (or even most) of the variability in meta-analytic linear Big Five—job performance investigations, which could be relevant for nonlinear cases. Johnson and Hezlett discuss findings from Tett and Christiansen (2007), who found an average 80 percent credibility interval of .3 across meta-analyses; thus sampling error alone could not account for the variability across studies.

While sampling error is at play in any set of psychological studies, the current study emphasizes the possible importance of substantive moderating variables. That is, there may be certain conditions under which it is more or less likely to observe nonlinear personality—job performance relationships. In particular, moderation could have two general effects: (a) influencing whether personality—performance relationships exhibit nonlinearity, and (b) influencing the point in the joint predictor and criterion score ranges at which the relationship departs from linearity. The focus in this study is on occupation-level moderators of the form of individual-level personality—performance relationships. *Individual-level* refers to the level of analysis in which each individual case has both personality and performance scores. In contrast, *occupation-level* refers to the fact that individuals are naturally grouped into various occupations, and each occupation is associated with a set of defining characteristics. At the occupation level, these characteristics are considered essentially constant within each occupational unit, such that each individual within an occupation has the same score on an occupation-level characteristic. An example is an occupation-level indicator of work autonomy: Many occupations differ in terms of the autonomy afforded to incumbents, but the difference

here is conceptualized to vary at the occupation level as opposed to the individual level. Thus, for the purposes of this study, occupation-level moderators differ from other possible ways of thinking about moderators, such as the particular job performance criterion of interest, personality predictor of interest, or environment in which a study was conducted (i.e., lab/field comparisons). The fundamental research question is: What are the conditions under which one might expect departure from linearity in personality—job performance investigations?

Out of those reviewed above, one study has examined a possible moderator for nonlinear personality—performance functional forms. Le et al. (2011) proposed that an occupation-level feature, job complexity, might affect whether or not nonlinear relationships are exhibited. They chose to investigate job complexity for three primary reasons: (a) this characteristic is a known moderator of cognitive ability—performance correlations (Hunter & Hunter, 1984), (b) it may provide an explanatory framework for any differences in findings across occupations, and (c) complexity information for an occupation is frequently available, as it is considered important. There are many possibilities for operationally defining job complexity, and Le et al. reported two techniques that differ between their two studies. In their first study, two researchers made dichotomous judgments (low complexity/high complexity) on the basis of written information about the jobs in question. The judgments integrated the degree of non-routine and complex information processing as well as the training and preparation needed. Le et al. found that job complexity moderated the conscientiousness—task performance relationship, such that the negative quadratic relationship changed from

positive to negative much lower in the score range for low complexity jobs than for high complexity. They also found that complexity moderated relationships of emotional stability with task performance and OCB; in both cases, the inflection point at which the form becomes negative occurred much lower in the personality score range for low complexity jobs, whereas the form effectively asymptotes at higher scores in high complexity jobs. In their second study, Le et al. operationally defined complexity using job zone data from the Department of Labor's Occupational Information Network (O*NET). Job zone data is based on the degree of vocational preparation needed for the job and takes into account experience, education, and training. While the conscientiousness and emotional stability—task performance findings did not replicate, complexity again moderated the negative quadratic emotional stability—OCB relationship in the same manner as study 1. Le et al. (2011) positioned these findings against Robie and Ryan's (1999) and LaHuis et al.'s (2005) previous studies involving conscientiousness: Where Robie and Ryan examined fairly complex jobs and found no evidence of curvilinearity, LaHuis et al. obtained significant quadratic effects in two samples of relatively low-complexity clerical occupations.

Research Question 6: Are the forms of relationships between personality predictors and performance moderated by omnibus indices of job complexity?

Possible Moderators in Addition to Job Complexity. The current study is intended to replicate Le et al.'s findings by examining the degree to which job complexity moderates the form of the relationships in the current samples. However, overall complexity indices are still somewhat of a “black box” in the sense that

occupations can vary in many different ways, leaving it unclear where a moderating effect lies. While indices such as O*NET's job zone can provide an omnibus test of moderation via job complexity, it is possible that examining occupation characteristics as moderators within a theoretical framework will provide additional explanatory power. Tett and Burnett (2003) provide just such a framework by arguing that there are job or situational characteristics that "activate" the expression of particular personality traits. According to Tett and Guterman (2000), when a trait is cued as relevant in a given situation, and the circumstances allow the actor opportunity to select a course of action, then one's standing on the trait becomes a determinant of the way they think, feel, or act. In the case of possible nonlinearity, the question becomes whether these characteristics activate trait expression similarly across the full range of the trait.

This study focuses on seven potential moderating characteristics, all of which relate to occupation-level work styles. Drawn from large-scale efforts to quantify the "personality loading" for various occupations, work styles are intended to indicate the degree of personality trait relevance to the performance of work activities. To the extent that occupations differ in terms of the importance of work styles, there may be utility in examining whether these characteristics function as moderators of individual-level personality—job performance relationships. Data on these characteristics are available in the form of mean ratings on Likert-type scales (e.g., capturing judgments of importance). For example, it is possible to ask, "For occupation X, how important is having a social orientation to performance of the job?" In terms of analytical design, the moderation question can be summarized as follows: Does the magnitude or direction of the quadratic

coefficient based on the regression of performance ratings on a personality scale depend on the rated importance level of the moderating characteristic? This summary question can be decomposed into two component research questions: (a) Does the moderator determine whether there is evidence for nonlinearity, in terms of the magnitude and practical significance of the quadratic regression coefficient? (b) In the case of a meaningful quadratic coefficient, does the moderator appear to determine the location at which a bend, or inflection point, occurs? One goal of this study is to examine these moderators where it is feasible to do so, as this represents an expansion of the path of inquiry started by Le et al. (2011). The set of work styles examined in this study is detailed below.

Occupation-relevant personality work styles. Growing general acceptance of personality measures in the workplace has included heightened interest in identifying personality-based characteristics that are useful in the performance of work activities as part of job analysis procedures. Two similar efforts in the late 1990's resulted in taxonomies of personality-based job analysis descriptors. Raymark et al. (1997) developed a deductive job analysis questionnaire intended to identify the degree to which work activities linked to each of the Big Five personality factors. Borman, Kubisiak, and Schneider (1999) reported a similar effort to identify dispositional requirements as a component of O*NET's Content Model. In an effort to balance construct clarity and empirical prediction, they drew from work on both the internal structure of personality (i.e., the Big Five) and the literature on predictive validity for personality concepts,

whether rooted in the Big Five or not. Borman et al. identified 17 (later revised to 16) descriptors that could be fully nested within 7 broader factors:

- (a) Achievement orientation – job requires personal goal setting, trying to succeed at those goals, and striving to be competent in own work
- (b) Social influence – job requires having an impact on others in the organization, and displaying energy and leadership
- (c) Interpersonal orientation – job requires being pleasant, cooperative, sensitive to others, easy to get along with, and having a preference for associating with other organization members
- (d) Adjustment – job requires maturity, poise, flexibility, and restraint to cope with pressure, stress, criticism, setbacks, personal and work-related problems, etc.
- (e) Conscientiousness – job requires dependability, commitment to doing the job correctly and carefully, and being trustworthy, accountable, and attentive to details
- (f) Independence – job requires developing one's own ways of doing things, guiding oneself with little or no supervision, and depending on oneself to get things done
- (g) Practical intelligence – job requires generating useful ideas and thinking things through logically

Previous research suggests that larger correlations are typically found when personality predictors are matched on a rational or theoretical basis with criteria, as

opposed the “shotgun” approach whereby everything gets correlated with everything else (Bartram, 2005; Hogan & Holland, 2003; Johnson & Hezlett, 2008; Tett et al., 1991).

However, that work focuses on the magnitude of correlations. The degree to which these occupation-level work styles influence the functional form of personality with performance remains to be seen.

This study focuses on the conceptual match between the individual-level personality characteristic and the occupation-level work style. The focal comparisons are listed here:

- (a) The form of individual conscientiousness—performance relationships may be moderated by the degree to which the Achievement Orientation and Conscientiousness work styles are important for an occupation.
- (b) The form of agreeableness—performance relationships may be moderated by the importance of Interpersonal Orientation for an occupation.
- (c) The form of emotional stability—performance relationships may be moderated by the importance of the Adjustment work style for the occupation.
- (d) The form of extraversion—performance relationships may be moderated by the importance of Social Influence for the occupation.
- (e) The form of openness—performance relationships may be moderated by the importance of the Practical Intelligence work style for the occupation.

Researchers have made suggestions about the extent to which occupation characteristics may either promote or inhibit the degree to which various individual standing on personality traits is related to performance. Barrick and Mount (1993) found

that the magnitude of validity coefficients for conscientiousness, extraversion, and agreeableness differed between high- and low-autonomy jobs. LaHuis et al. (2005) suggested that low autonomy might contribute to finding nonlinearity, as lack of autonomy may place a ceiling effect on whether higher scores on conscientiousness can influence performance. In essence, low autonomy might create a “strong situation” that would inhibit manifestation of the full range of the personality characteristic. Building on this idea, Converse and Oswald (2012) proposed that high levels of conscientiousness may be maladaptive in occupations requiring adaptability and flexibility: Increasing information input and processing requirements may lead those high on conscientiousness to get bogged down with details. Similar concepts could be true for other Big Five factors. For instance, those scoring high on extraversion may not display that tendency in work environments entailing minimal interaction; conversely they may be unable to restrain their social tendencies, leaving others feeling dominated in team settings. Additionally, agreeableness may have an asymptotic or negative quadratic relationship with performance in occupations where conflict might occur: Those high in agreeableness may not behave assertively enough or react appropriately in conflict situations. Finally, those very high on openness may become distracted by the abundant informational stimuli and be unable to focus on completing tasks.

By directly examining job analytic ratings of personality importance, the goal is to understand how these characteristics operate using data from organizations.

Research Question 7: Are the forms of relationships between personality predictors and performance moderated by occupation-level factors such as task characteristics, work styles, the social context, or occupation-relevant interests?

Study Overview

The objective of the current study is to examine linear and nonlinear relationships between Big Five personality measures and job performance using available data from a single personality instrument: the Hogan Personality Inventory (HPI). Using one instrument permits clarity in the inferences that can be drawn from results. In addition, considerable effort has been undertaken to establish that the HPI can be interpreted within the broader Big Five construct literature (Hogan & Hogan, 2007; Hogan & Holland, 2003). Thus, examination of a large HPI database allows for a replication and extension for the Big Five factors that have been studied previously using Big Five-oriented scales (conscientiousness, openness, and emotional stability). A potential disadvantage to focusing on one inventory is that the specification of exact bend or inflection points for any nonlinear relationship may be inventory-specific. Thus the generalizability of a specific turning point in the predictor score range may be questionable.

This study provides the first major analyses for extraversion and agreeableness. The scant previous evidence in these domains has been drawn from measures not explicitly targeting the conceptual level of the Big Five. Importantly, the HPI validation database also contains Standard Occupational Classification (SOC) codes that permit links to the Department of Labor's (DOL) O*NET database. This feature allows for

examination of the potential job complexity and work style moderators listed above, consistent with proponents of Trait Activation Theory (Christiansen & Tett, 2008).

Thus, compared to existing studies in this domain, the current effort brings to bear a larger database than ever before, based on one of the most widely used and accepted personality assessments in applied psychology. Data spanning seven job families were available, representing many settings. Finally, links to the O*NET allowed for integration of a large, nationally representative and systematically-sampled job analysis system with the personality data to examine potential moderators.

SECTION 2: METHOD

Sample

Data were drawn from test validation research conducted by Hogan Assessment Systems. No new participants were tested for the specific purposes of this study. Participants were drawn from 123 validity studies conducted in support of using the Hogan Personality Inventory (HPI) scales as a set of predictor variables. Performance rating data, detailed below, were collected and categorized according to a dimensional model of job behavior. The largest sample sizes for analyses involving overall job performance ranged from 11,312 to 12,216; analyses involving other criteria were smaller (further details are found in the results section and associated tables). The sample included studies with participants distributed among seven job families: managers and executives, professionals, technicians and specialists, sales and customer support, administrative and clerical, operations and trades, and service and support (Table 1). Participants were distributed across occupations ranging from low complexity to high

complexity, as defined using the DOL O*NET's job zone classification system, described below (Table 1; see also Oswald, Campbell, McCloy, Rivkin, & Lewis, 1999).

Information on the gender, ethnic diversity, age, and tenure of the sample is shown in Tables 2 and 3.

Measures

Hogan Personality Inventory (HPI). According to Hogan Assessment Systems, the HPI was the first inventory of normal-range personality based on the Big Five designed specifically for workplace use. The HPI consists of 206 true/false items that are combined into 41 homogenous item clusters (HICs) based on common themes and empirical correlations among items. In turn, these HICs form seven composite scales used operationally (descriptions are based on the HPI Manual [Hogan & Hogan, 1995], with the Big Five corollary in parentheses):

- (a) *Adjustment* (emotional stability): confidence, self-esteem, and composure under pressure
- (b) *Ambition* (extraversion): initiative, competitiveness, and desire for leadership roles
- (c) *Sociability* (extraversion): extraversion, gregariousness, and need for social interaction
- (d) *Interpersonal Sensitivity* (agreeableness): tact, perceptiveness, and ability maintain relationships
- (e) *Prudence* (conscientiousness): self-discipline, responsibility, and conscientiousness

(f) *Inquisitive* (openness to experience): imagination, curiosity, and creative potential

(g) *Learning Approach* (openness to experience): achievement-oriented and up-to-date on business and technical matters

The HPI manual (2007) describes test reliability for each of these scales as being in the .69 to .87 range. Hogan and Holland (2003) also report recent reliability estimates, where the first value indicates internal consistency and the second indicates test-retest: Adjustment (.89/.86), Ambition (.86/.83), Sociability (.83/.79), Likeability/Interpersonal Sensitivity (.71/.80), Prudence (.78/.74), Intellectance/Inquisitive (.78/.83), and School Success/Learning Approach (.75/.86). All items were written targeting a fourth grade reading level and have been reviewed for content based on professional standards. The HPI has been used frequently in research settings, and is generally accepted among practitioners and the academic community. Construct validity evidence for the HPI's relevance to the Big Five framework has been established in several major studies (Hogan & Hogan, 1995; Hogan & Hogan, 2007; Hogan & Holland, 2003). The HPI is at least as technically adequate as any comparable instrument, is associated with a long history of supporting research, and has been used widely for workplace assessment. Construct validation is certainly an ongoing process with implications for the degree to which results from the current study can be generalized to settings in which alternative personality inventories are administered (Anderson & Ones, 2003; Hough et al., 1990).

The Big Five bandwidth is the primary focus of this study, and the analyses and results use the Big Five labels instead of the HPI scale labels. The HPI archive examined

in this study did not include individual scales mirroring the bandwidth of the extraversion and openness to experience Big Five factors. The reason is that the concepts of Ambition and Sociability, both linked to extraversion, could be said to tap into conceptually distinct aspects of extraversion. The same argument can be made for the relationships of Inquisitive and Learning Approach scales to openness to experience. Thus these HPI scales were developed in a manner consistent with Hough's (1992) arguments that Big Five-bandwidth scales can obscure facet-level measurement properties. To provide proxies for Big Five extraversion and openness, and thereby to provide some comparison to other studies at the Big Five level, these two groupings of "facet" scales were combined into unit weighted scales representing extraversion and openness (e.g., Bobko, Roth, & Buster, 2007). Descriptive statistics for the personality predictor scales are shown in Table 4. Correlations among the scales are shown in Table 7.

Job performance. Performance ratings were collected for research purposes and were based on the domain competency model described by Hogan, Davies, and Hogan (2007) and Hogan Assessment Systems (2009). Thus, in this study the term "competency" refers to a behavioral performance component on which individuals are thought to vary. Supervisors provided numeric competency ratings for those who completed the HPI. In each validation study, the rated performance competencies were included on the basis of a job analysis procedure. The studies examined in the present research were drawn from a mix of predictive and concurrent validation designs, with the large majority from concurrent studies. Hogan et al. (2007) provided rational crosswalks of their domain model to performance models suggested in the literature (e.g., Bartram,

2005; Borman & Motowidlo, 1993; Campbell, McCloy, Oppler, & Sager, 1993; Hunt, 1996, Tett, Guterman, Bleier, & Murphy, 2000), arguing that their domain model can subsume these models. While this is a broad claim, it is consistent with recent suggestions from Campbell (2012), who argued that most professionally developed multidimensional models of occupational performance refer to the same fundamental behavioral concepts, even if they use different labels. Following consideration of the measurement properties of the conceptually multidimensional competency ratings, an index of overall job performance was determined to be the best available criterion for this study. The following paragraphs provide details about this decision.

The four domains in the model used by Hogan et al. (2007) are intrapersonal skills, interpersonal skills, technical skills, and leadership skills. In spite of the use of the term “skills”, these classifications refer to substantive domains of employee behaviors, as opposed to performance determinants. One goal of this study was to examine performance information in such a way as to provide information about task performance, OCB, and CWB. These three performance categories have been shown to be relevant in the work environment, conceptually and empirically distinct (Dalal, 2005; Rotundo & Sackett, 2002), and consistent with other models such as that provided by Campbell et al. (1993). Concepts of task, OCB, and CWB performance were also studied in the work of Le et al. (2011) described above. It appears possible to link the Rotundo and Sackett three-component framework to the Hogan competency model on a rational basis. First, the component of *work skill* from the Hogan et al. model refers to the proficiency with which one assimilates and works with information and solves work-

related problems. This dimension essentially refers to the core technical component of job performance – often labeled task performance. Example competencies linked to technical skill in this model included Industry Knowledge, Information Analysis, Presentation Skills, and Problem Solving. Thus these ratings were the closest available proxy to an index of the proficiency with which an employee performs work activities that involve specific technical matters. Second, Hogan et al.'s concept of *intrapersonal skills* concerns the degree to which employees maintain self-esteem, resilience, and emotional security, as well as the degree to which they exercise self-control. Thus, high intrapersonal performance could be seen as avoidance of CWB, with example competencies including Professionalism, Following Procedures, Responsibility, and Work Ethic. These concepts correspond to the Maintaining Personal Discipline performance component discussed by Campbell, McHenry, and Wise (1990). Third, Hogan et al.'s *interpersonal skill* competency refers to the degree to which employees are rewarding to work with, contribute positively to the work environment, and are empathetic towards others. This domain is comprised of competencies such as Organizational Citizenship, Service Orientation, Building Relationships, and Teamwork. These behaviors appear to match well with concepts of OCB and contextual performance offered by Borman and Motowidlo (1993) and Organ (1997). Finally, the concept of *leadership skill* is based on recruiting, managing, and planning work for others. Sample competencies included Managing Conflict, Motivating Others, Employee Development, and Resource Management. These leadership competencies were not restricted to use in studies with participants holding formal leadership or managerial roles, but do tend to be

emphasized more heavily in those settings. The development of the four performance components in the domain model is described in Hogan and Warrenfeltz (2003) and a white paper from Hogan Assessment Systems (2009).

The four broad performance components described above can be characterized as overlapping both conceptually and empirically. Conceptually, the behaviors involved in performing leadership work also often have both interpersonal (Building Teams) and intrapersonal (Managing Conflict) components. Some competencies categorized in the more technically focused *work skill* domain also relate to interpersonal concepts, such as Negotiation or Sales Ability. From a measurement standpoint, all competency data were collected via supervisor ratings. The use of a common method can contribute to the magnitude of correlations among different competency ratings for both substantive and non-substantive reasons (Podsakoff et al., 2003). On one hand, an employee may be rated at a similar level across performance components due to commonalities in the judged effectiveness of those specific behaviors, or perhaps due to performance in conceptually separable domains that share determinants (Viswesvaran, Schmidt, & Ones, 2005). On the other hand, ratings on multiple competencies may covary due to a rater's holistic evaluative judgment about an employee's behavior or contribution, largely irrespective of the substance of the rating stimulus. Composites for the intrapersonal, interpersonal, leadership, and work skill domains were formed, each consisting of the available component competencies rated within a given validity study. Descriptive information for the performance ratings is shown in Tables 5 and 6. Correlations among the performance composites are shown in Table 7, and range from .61 to .75, uncorrected for measurement

error. Although it may be desirable to conduct a factor analysis on the competency ratings as a further empirical examination of their dimensionality, such an analysis was not feasible due to missing values in the correlation (or covariance) matrix for all competencies. That is, since many performance competency pairs were never included together in a study, even a pairwise matrix could not be assembled for submission to factor analysis.

A feature of the archival database is that most validity studies incorporated ratings across differing sets of competencies. That is, different groupings of competencies were available for each validity study. The primary reason for this is that the final set of competencies included on validation study performance rating forms was selected based on importance ratings from a job analysis questionnaire. While the goal was to draw some inference about each of the four performance domains (not including overall performance), it also meant that the competencies comprising the domain composite differed somewhat across validity studies. Every competency rating in the database was available on a standardized scale. To provide an estimate of reliability or consistency within each domain, the average correlation among competency ratings within each domain was obtained. This correlation estimate was then entered into the Spearman-Brown formula to estimate an intraclass correlation based on the average number of competencies making up the composite. These estimates are shown in Table 8, and show that several of the domain-specific criteria are estimated to have low reliability (.5 to .6) when operationally defined as composites in the manner done in this study. In lieu of a factor analysis, to examine the dimensionality of the individual competency ratings, a set

of divergent (between-domain) correlations was calculated for comparison with the convergent (within-domain) correlations in Table 8. For example, the mean correlation of competencies categorized as “intrapersonal” with competencies not categorized as “intrapersonal” (labeled “other” in Table 8) was obtained. All of these correlations were calculated within each validity study and the results represent weighted averages across the studies. The data in Table 8 show that the convergent and divergent correlations were of nearly the same magnitude (all fell within a range from .40 to .47), suggesting that the conceptual differences between criteria were not borne out empirically.

Given all of the above, overall job performance was selected as the focal criterion domain for four primary reasons. First, as shown above, the convergent and divergent correlations among performance ratings indicated that these data contained virtually no empirical properties for differentiating among performance domains. Analyses for each criterion domain were conducted on the basis of the conceptual distinctions described above for exploratory purposes, but the correlations suggest strong positive manifold across the ratings. Second, research indicates that composite measures of overall performance can be derived from conceptually distinct performance measures, whereby those who perform well in one domain of performance also tend to perform well in other domains (Viswesvaran et al., 2005). The correlations among the four composite criteria suggest the presence of a large general performance factor. Overall performance can be said to provide an indication of one’s economic value in the pursuit of organizational goals (Schmidt & Kaplan, 1971). Third, overall job performance data were available for virtually all of the validity studies available for analysis, and thus yielded an opportunity

to maximize the sample size for this set of analyses while still allowing for substantive conclusions to be drawn. Fourth, a final advantage is that examination of overall job performance permits comparison with findings from previous studies. Overall job performance represented summary judgments made by raters regarding the effectiveness of an employee's job behavior. As with the four criteria described above for the domain model, overall job performance ratings were available in a standardized metric (mean of 0 and standard deviation of 1). As an indirect indicator of reliability, the same procedure used to estimate ICCs for the other performance composites was applied to the full set of correlations among competencies. Given an average of 10.52 competencies rated per study and mean correlation among competencies at .43, an approximate ICC for an overall performance composite was .89. Note that this estimate is a within-rater (intrarater) reliability estimate: The interrater reliability of these performance ratings is not addressed here due to the unavailability of data. An interrater reliability estimate would be needed if one were to correct for unreliability (Schmidt & Hunter, 1996).

Occupation Characteristics from O*NET. The O*NET database provides a repository of rigorously collected occupational information. These data were drawn from the Department of Labor's (DOL) website to form the moderator variables in this study. The validity studies in the Hogan Archive were coded using the DOL's Standard Occupational Classification (SOC) scheme. The SOC coding in the HPI database is the key feature that allows the link between the personality-based validity evidence and the O*NET information. To date, a primary use of the HPI's SOC linkage is to allow for

internal validity generalization studies in support of a given client organization's use of the HPI. The current study uses this linkage for somewhat broader research purposes.

The O*NET contains job-analytic data that are systematically sampled from many occupations throughout the U.S. economy. The database available at the time of this study, O*NET 17.0, contains updated data representing 900 occupations. O*NET data are organized using a Content Model that allows for occupations to be evaluated on over 250 characteristics within 6 major categories. The O*NET 17.0 development database was obtained from the DOL's website: <http://www.onetcenter.org/>. O*NET lists 1,110 occupations in the current SOC, although over 100 occupations do not presently have data collected. Each occupation for which data exists has been evaluated either by job incumbents (those who regularly perform the work), occupational analysts (those who have specialized training in job analysis techniques), occupational experts (those who are involved in a professional association relevant to a particular occupation), or a combination of these three data sources.

Similar to Le et al.'s (2011) second study, this study adopts O*NET's job zone as an index of overall job complexity. The job zone corresponds with typical educational requirements and experience needed, although it is also assigned on the basis of vocational training, consistent with previous classifications in the Dictionary of Occupational Titles (Oswald, Campbell, McCloy, Rivkin, & Lewis, 1999). Each occupation is assigned a numerical job zone code, which is defined by the following 5-point scale:

- 1 = Little or no preparation needed (less than high school);

- 2 = Some preparation needed (high school diploma);
- 3 = Medium preparation needed (high school plus);
- 4 = Considerable preparation needed (bachelor's degree); and
- 5 = Extensive preparation needed (bachelor's degree plus).

As job zone assignments take into account education, experience, and training, the ratings are similar to complexity information used in previous studies, namely Hunter's (1983) examination of General Aptitude Test Battery (GATB) validity. The DOL provides additional information on the job zone classification system at the following internet address: <http://online.onetcenter.org/help/online/zones>.

O*NET's Content Model essentially defines the taxonomy for each of the domains from which potential moderating variables are drawn in this study. Ratings of personality trait relevance to performance of the occupation were taken from O*NET's taxonomy of work styles. The current work styles taxonomy includes 16 rated descriptors representing the importance of the trait for performance, which were combined into the following seven composite variables (with number of component descriptors in parentheses): achievement orientation (3), social influence (1), interpersonal orientation (3), adjustment (3), conscientiousness (3), independence (1), and practical intelligence (2). Evaluators rate work style descriptors in terms of their importance to performance on a 5-point Likert scale, where *1 = Not Important*, *2 = Somewhat Important*, *3 = Important*, *4 = Very Important*, and *5 = Extremely Important*. Most of the work style variables involved calculation of composite variables. Overall descriptive statistics, internal consistency estimates where feasible, and correlations among moderators were

examined. This descriptive information is presented in Table 9. Primarily, this was done to examine the composite variables used in this study, adding to the conceptual and empirical rationale that already exists in the form of the hierarchical descriptor taxonomies in O*NET's Content Model (Borman et al., 1999). The distributions for these variables were also examined.

One other comment on the use of O*NET data is relevant here: These data were not collected for the specific organizations represented within the HPI database save for unlikely chance overlap; thus the O*NET data represent typical occupational characteristics, as opposed to the characteristics within the specific organizations from which the personality—performance validity data are drawn. While in some ways this could be considered a strength, such as in avoidance of potential common method variance (i.e., single source) confounds, this feature is important for interpreting results, as findings may differ in cases where personality, performance, and occupational characteristic data are collected within the same organizational context.

Data Analysis

Descriptive statistics. A series of analyses were planned to evaluate the research questions in this study. Descriptive statistics were examined for all variables, including calculation of means, standard deviations, scale score ranges, and distributional characteristics (i.e., skewness). Similar analyses were also conducted within each of the validity studies. Although important for any study, distributional characteristics are particularly important in this study, as the frequency of personality scores at the high end of the scale can affect the degree to which nonlinearity is a concern.

Nonlinearity analyses. Building on the descriptive analyses, correlations between each personality predictor and each criterion variable were examined. The focal analyses for nonlinearity were drawn in part from procedural recommendations for hierarchical polynomial regression analyses described by Cohen et al. (2003). Polynomial regression techniques are associated with the highest statistical power for analyses of this type, especially in comparison to statistics such as the correlation ratio (Coward & Sackett, 1990). In addition to the descriptive analyses described above, the first step in examining the form of the personality—performance relationships is plotting the data. For each personality predictor, scatterplots of the joint relationship with each criterion domain were generated. Loess curves were superimposed on the scatterplots, as they are nonparametric curves that completely follow the data; that is, they are not based on a linear fit coefficient such as a correlation or regression coefficient. Loess curves connect the means of Y across specific values of X. An additional virtue of scatterplots is that, along with descriptive statistics, they can be useful in the detection of outliers.

A second set of residual scatterplots was generated. These graphs were based on residuals from a linear regression of each criterion on each predictor. Following estimation of the linear regression, the residuals were plotted on the Y axis (ordinate) against the predictor on the X axis (abscissa). The advantage to the residual plots is that they allow for inspection of the relationship that was not predicted by the linear equation. That is, once the linear trend is accounted for, is there evidence for a predictable curvilinear trend? These two sets of plots were generated for each predictor—criterion combination using the full available database.

The hierarchical power polynomial regression approach proceeded in several phases. The general equation used in analyses of this type – and adopted in virtually all studies of nonlinearity reported above – is as follows:

$$\hat{Y} = B_1X + B_2X^2 + B_0 + e$$

Prior to analysis, the each predictor is centered so that the mean score becomes equal to 0. Following the recommendations of Cohen et al. (2003) and Enders and Tofighi (2007), predictors were group mean centered in this study. A set of overall analyses were conducted that were identical in all analytical aspects except group mean versus grand mean centering; the results were very similar and the group mean centered results will be the focus from this point forward. Procedurally, centering was done by subtracting the group mean (with group in this case being each validity study) from each predictor variable. In addition to providing interpretational advantages for the subsequent regression results, which gives the 0 point a meaningful value, centering removes nonessential collinearity among the predictors. This helps address multicollinearity, which is a particular issue in polynomial regression, as the higher-order polynomial terms are formed using the lowest-order (linear) term. Once the linear predictor is centered, higher-order centered predictors are formed from the centered linear predictor. This is accomplished by squaring the linear term. For all analyses not incorporating continuous moderator variables (described in more detail below), the analytic strategy involved estimating a set of regression coefficients within each validity study and calculating a sample-size-weighted average of the results. The consequence for the centering decision is that such within-study analyses end up being equivalent whether one is interested in

grand mean or group mean centering, since each group is analyzed separately. For multilevel modeling analyses, centering plays a more important role since all available groups are analyzed simultaneously. Group mean centering was used for those analyses, as it is the recommended procedure when cross-level interactions are of interest with cross-sectional data (Enders & Tofighi, 2007).

The regression analyses were conducted by entering the centered personality variable of interest as the sole predictor in step one. The squared value of that centered variable was then entered as the second predictor in step two, and change in variance explained statistics (R^2), along with the magnitude, direction, and significance of the polynomial/quadratic coefficient, were interpreted. The equation was then plotted for interpretation. Two additional pieces of information were examined: (a) simple slopes and (b) location of bend points. The equation for calculating simple slopes in this case was (Cohen et al., 2003):

$$B_1 + 2B_2X$$

Simple slopes provide information about the linear regression of performance on the personality predictor, and can be calculated for an X value of interest. Thus the slope can be evaluated at multiple points along the predictor score distribution. In this case, simple slopes were calculated for predictor scores at -2 SDs, -1 SD, the mean, +1 SD, +2 SDs, and +3 SDs. Alternatively, bend points occur where the slope of the regression line changes sign (an inflection point) or meaningfully departs from linearity. For a negative quadratic coefficient, the latter issue can be characterized as the point at which, after reaching an optimal level in association with performance, higher personality scale scores

become suboptimal. Cohen et al. (2003) provide the following formula for estimating the bend point of interest:

$$X_M = \frac{-B_1}{2B_2}$$

Where X_M refers to the maximum point for a negative quadratic with a negative regression coefficient (indicating an inverted-U), or a minimum point for a quadratic with a positive coefficient (a U-shaped relationship). The associated formula for determining the criterion score at X_M is given by:

$$Y_M = \frac{4(B_2)(B_0) - B_1^2}{4(B_2)}$$

In some settings the point at which a line meaningfully changes in slope but does not change its sign (positive to negative, and vice versa) is referred to as an undulation point. Terminology aside, these analyses provide insight into the peak level of each personality trait (as measured by the HPI) for performance. Of particular interest is whether these values fall within the range of observed scores for each personality characteristic.

The analytic strategy for the hierarchical polynomial regressions involved running the analysis within each validity study separately and aggregating the results. This was done to account for any non-substantive between-study differences that introduce nonindependence in the data. There may be some variance attributable to validity study membership that could influence the results, such as company norms for making performance ratings, ways in which data were collected differing across studies, or organizational climate conditions at the time of the study. Conducting each analysis within each study and weighting the results by sample size helps to control for this

variance, which is construed here as artifactual. As detailed below, the multilevel modeling approach represents another way to handle similar analyses, and is used to examine moderators in this study.

Analyses for recommended operational scales. All of the above analyses make use of the full available database for each predictor. Additional analyses were conducted in which the database for each Big Five predictor was restricted to studies in which that scale was subsequently recommended for operational assessment use. That is, for each predictor, studies were only included if the predictor was recommended by Hogan Assessment Systems for use in the organization on the basis of their validity study. The premise for these analyses is that the implications of nonlinearity for operational assessment are most relevant in situations where the predictor would actually be used. The rationale is similar to the “confirmatory” approach taken by Tett et al. (1991). For conscientiousness, agreeableness, and emotional stability, studies were only included if the Prudence, Interpersonal Sensitivity, and Adjustment scales (respectively) were recommended. For openness and extraversion, studies were included if either of their HPI component scales were recommended. Information about whether each scale was recommended was obtained from technical reports for each available validity study.

Summary. Davison (personal communication) provides an additional rationale for the quadratic regression approach. On the basis of criterion-related pattern and profile analysis (e.g., Davison & Davenport, 2002), an individual’s scores on a personality predictor can be conceptualized as deviations from an optimal profile of predictor scores for predicting a criterion of interest. Profile match scores can be calculated as a squared

profile match measure; for instance, a squared Euclidean distance. This squared distance term functions as a quadratic term in the regression model, and can capture a nonlinear predictor-criterion relationship. Note that full capitalization on a criterion-related profile occurs in cases with multiple predictors, such that a profile across a set of independent variables can be identified. The focal analyses in this study are based on the examination of personality scales individually in separate regression models.

Several overarching comments about the power polynomial approach are warranted. First, nonindependence of the data, and thus the residuals from a regression analysis using data compiled across validity studies, may be an issue (Kenny & La Voie, 1985). Thus, intraclass correlations (described in more detail below) were calculated and examined as an indication of the degree to which variance in each criterion is attributable to validity-study-level effects. In all cases, these intraclass correlations were approximately equal to 0. Nonetheless, two procedures were used to ensure that the hierarchical polynomial regression procedure avoids conflating between and within-study effects: (a) calculating regressions within unit and sample-size weighting the resulting coefficients of interest, as described above, and (b) using multilevel modeling techniques, described below, for moderation analyses.

Second, interpretation of the shape of the regression function, as well as the weights used to calculate simple slopes and inflection points, are based on the regression coefficients for the highest-order predictor (the quadratic term), in the context of the fully specified polynomial equation. While these analytical procedures are generally accepted, Cohen et al. (2003) note that polynomial equations may only be approximations to

nonlinear relationships. In a related point, the goal of this study is to not be a “curve-fitting” exercise: While the regression models are a centerpiece of the analyses, understanding the implications associated with the observed data, not just regression fit, is important. One way to examine this issue is to use a procedure similar to Coward and Sackett (1990), where the number of statistically significant quadratic coefficients is tabulated. While this procedure provides no information about effect size (Ones et al., 2007), it provides an indication of how frequently a quadratic coefficient is found to be statistically significant, and can be compared to commonly accepted chance base rates (i.e., .05). Findings of statistical significance are often relied on heavily in polynomial regressions in the personality domain, so this count can be informative.

Moderator Analyses. Multilevel modeling (MLM) was used to examine both the nonlinearity analysis questions and moderation hypotheses, since employees were nested within occupations differing in the characteristics outlined above. As described above, the personality and performance measures in this study were conceptualized at the individual person level, which can in turn be considered level-1 variables here. In this study, moderating variables of interest all refer to occupation-level characteristics, which were considered level-2 variables. Thus the occupational characteristics take on the same value for all cases within an occupation but take on varying values across occupations. If analyzed with “standard” regression procedures – those that do not take into account the nested data structure – standard errors would be biased, in turn rendering statistical significance tests biased at best or misleading and uninterpretable at worst (Bliese, 2000; Bliese & Hanges, 2004; Raudenbush & Bryk, 2002).

For the purposes of this study, MLM analyses were associated with two key virtues. The first was the ability to estimate the proportion of variance in the performance variable attributable to both level-1 and level-2 units. Such an analysis indicated the degree to which validity study nesting contributes to variance in performance. (Note that validity study and organizational nesting were functionally equivalent in this case.) As above, the degree to which one's membership in a particular organization or validity study can influence the ratio of within-organization to across-organization variance is an open question. That is, might the circumstances surrounding a particular validity study or the differing conditions across organizations lead performance ratings to be more similar within organizations (or validity studies) than across organizations (or studies)? In this case, the occupation-level moderators would still be of interest, but the units responsible for nesting would be organizations.

Analytically, these variance proportions were estimated with an unconditional multilevel model, where the dependent variable was estimated as a function of the grand mean, validity-study-specific deviations, and a residual reflecting individual case differences from their validity study's mean (Hofmann, Griffin, & Gavin, 2000; Peugh & Enders, 2005). Variance estimates for level-1 and level-2 residuals that resulted from this estimation were used to calculate an intraclass correlation (ICC), which indicated the proportion of variance between level-2 units. Larger ICCs indicated larger effects of the level-2 units.

The second virtue was the ability to take into account the nested data structure to estimate moderator effects in the form of cross-level interactions (Davison, Kwak, Seo, &

Choi, 2002). The fundamental, broad question of interest was whether the association between personality and performance was dependent on the occupational characteristic. Put another way, one could ask whether a level-2 variable predicts variation in the relationship between a level-1 predictor and criterion. A more specific cross-level interaction research question could take the following form: Does the rated importance of achievement orientation for an occupation predict the linear and curvilinear effects of conscientiousness on task performance? The ICC from the unconditional model provides one signal of the necessity for such an analysis; in other words, the ICC may signal that the level-2 variable has an influence. With an ICC approximating zero, study-level characteristics may be unlikely to exert a meaningful moderating influence. However, there is no general agreement on the ICC magnitude that meets a threshold for importance, and the ICC is certainly not an indicator of the significance of a main effect or interaction effect. Thus it is critical to note that such analyses proceeded on the basis of a judgment call that considered the magnitude of the ICC, the significance of the level-1 and level-2 variance components, the broad set of research questions, and the theoretical rationale for the moderating characteristic.

The analytic sequence for the moderator variables proceeded in the following manner. MLM procedures were conducted in four steps, consistent with procedures reported by Le et al. (2011). The first step involved estimating an ICC for the criterion variable and validity study identifier. The remaining steps involved multilevel regressions with predictors added in each step: Building on the unconditional model, the level-2 moderator main effect was added (step 1), the level-1 linear mean effect term was added

(step 2), the level-1 quadratic main effect term was added (step 3), and moderator interaction terms with the level-1 linear and quadratic predictors were added (step 4). Results of moderation analyses were plotted to further examine the effects.

Given the large scope of these analyses, the moderators were examined only for the overall job performance criterion. Each multilevel modeling analysis is accompanied with two sets of regression coefficients. The first contains the full model multilevel regression coefficients for each predictor, criterion, and moderator combination. The second contains the regression coefficients for -1 SD, +1 SD, and the mean level of the moderator variable. These coefficients enable plotting and examination of whether the inflection point varies meaningfully across moderator levels. This second set of regression equations was calculated using the procedure derived by Le et al. (2011, p. 119; see also Cohen et al., 2003, p. 293), in which the full regression equation was rearranged to yield coefficients for specified levels of the moderator. Each result table containing regression estimates for high, low, and mean moderator settings also contains inflection point estimates for both centered and standardized predictor scaling.

Finally, several possibilities for estimating pseudo- R^2 exist in multilevel modeling, although there is no direct analogue to the standard R^2 usually reported for single-level regression. Following recommendations from Hofmann, Griffin, and Gavin (2000), the current R^2 is based on estimation of percentage of within-group variance accounted for by each set of predictors relative to the total within-group variance estimated in an unconditional multilevel model (equivalent to a one-way ANOVA with no predictors/covariates). This equation allows for direct comparison to similar studies of

this nature (e.g., Le et al., 2011) and also allows for a consistent R^2 estimate at each step of the multilevel modeling procedure. The drawback is that this method occasionally yields negative pseudo- R^2 estimates when predictors are added to the model (Snijders & Bosker, 1994) – a counterintuitive result when compared to typical interpretation of R^2 in a regression framework. Generally, this occurs because the pseudo- R^2 in multilevel modeling is an indicator of reduction in variance components relative to the unconditional model, and some predictors either do not change the within-group variance component estimate or can actually increase it. Some investigators may choose to estimate R^2 using a different set of variance components depending on the “level” of each predictor added to the model (i.e., a different baseline model for each comparison). However, this can result in a different equation for R^2 at each level of the modeling procedure (Gelman & Pardoe, 2006); arguably this makes comparison across all R^2 even more complex. Alternative formulas for those estimates have been proposed (Snijders & Bosker, 1994). Finally, each result table contains inflection point estimates for both raw and standardized predictor scaling.

SECTION 3: RESULTS

Descriptive Information

Demographic and descriptive information for study variables are shown in Tables 1 through 9, and were discussed in the Method section above. Distributional information is of particular interest in studies of this nature, so predictor data were plotted (Figure 2) and skewness statistics are reported in Table 4 for predictors and Table 5 for criteria. Examination of skewness suggests that the Agreeableness scale exhibited negative skew.

None of the criterion variables had skewness statistics approaching an absolute value of 1, and thus skewness was not determined to be problematic for this study. Still, interpretation of analyses involving the Agreeableness scale should include consideration of these findings. Prior to the polynomial regression analyses, the above descriptive information was examined for each validity study with the general goal of identifying any potentially aberrant studies. No studies were removed on the basis of this review, perhaps due to the periodic cleaning and upkeep of the data archive by Hogan Assessment Systems.

Primary Nonlinearity Analyses

Graphical Displays. A series of loess curve graphs were examined following recommendations from Cohen et al. (2003). The smoothing parameter for each loess curve was fit with 50% of points. This parameter defines the proportion of observations used in each local regression. Decreasing this number results in the curve being more susceptible to influence by idiosyncrasies in each section of the score range, whereas larger values of this parameter result in smoother curves with the potential to overfit the data (Jacoby, 2000). The large number of observations in these graphs also helps avoid idiosyncratic fitting of the loess curve. The loess curves fitting the scatterplot for each predictor in comparison to overall job performance are shown in Figure 3. The general conclusion is that there is minimal visual evidence of departure from linearity for most of the predictors. Although the loess curve for Conscientiousness displays some fluctuation in the form of a negative quadratic at the high end of the scale, it is worth noting that the Y-axis (job performance) is scaled from -1 to +1 SDs in all figures, and that widening the

range can have the effect of reducing any graphed departure from linearity. Scatterplots and loess curves were also obtained and examined for each validity study, but are not included here due to space concerns.

Hierarchical Polynomial Regression Results

This section provides results of the sample-weighted hierarchical regression and multilevel modeling procedures, organized by predictor. The position taken here is that judgments about the presence and nature of curvilinearity should consider several aspects of the results of these analyses: the statistical significance of the quadratic multilevel regression coefficients, weighted mean regression coefficients and multiple R's, simple slopes, location of bend points, and graphical display of the full regression model. Results are organized by predictor, with moderation analyses following the regression results. Results for the alternative criterion domains are presented for completeness, but are not emphasized due to the lack of empirical basis for differentiating between criteria in this study. Thus strong caution is urged in interpreting any differences across criteria.

Conscientiousness Results. Research question 1 addresses the conscientiousness—performance relationship. Compiled results for the relevant analyses are shown in Tables 10, 11, and 12, and displayed graphically in Figure 4. The findings for Conscientiousness—overall job performance suggest a negative quadratic (change in $R = .04$; Table 10), where the relationship has a positive slope through most of the score range, but flattens out above 2 SDs above the mean (Figure 4, top left). However, the first column of coefficients in Table 11 shows that the multilevel quadratic coefficient was not statistically significant. The slope was estimated to change direction at 1.76 SDs above

the mean, equivalent to a raw score of 28 out of a maximum of 31 (Table 12). This pattern is consistent with the loess curve for Conscientiousness in Figure 3 (top left), although the lack of statistical significance calls into question whether the quadratic pattern is meaningful. While these very high scores have the potential to be suboptimal for performance compared to a linear trend, any total potential performance loss is likely to be minimal (cf., Converse & Oswald, 2012). Returning to the full sample of observed Conscientiousness raw scores, 569 out of 13,056, or 4%, scored in this area of the range. Figure 4 shows that for each criterion examined, Conscientiousness displayed a slight negative quadratic effect very high in the score range.

Conscientiousness—Overall Performance Moderation Analyses. As detailed in the Method section, ICCs were calculated for each analysis using the level-1 and level-2 variance components in the unconditional model. In all cases, the ICCs were approximately zero and thus are not reported for each analysis below. Although this finding suggests minimal variation in performance ratings across validity studies, the MLM procedure is still the recommended procedure for accounting for any cross-study effects attributable to the fact that individuals were naturally grouped within validity study.

Table 11 shows that none of the moderation analyses for the Conscientiousness predictor produced statistically significant results. Nonetheless, the results are plotted in the final three components of Figure 4 for the sake of completeness. These figures suggest visual evidence for slight differences in multilevel regressions across moderator

levels, but strong caution is urged in interpretation of these findings given the lack of statistical significance.

Agreeableness Results. Research question 2 addresses the agreeableness—performance relationship. Compiled results for the relevant analyses are shown in Tables 13, 14, and 12, and displayed graphically in Figure 5. The results for the Agreeableness scale suggest an unambiguously linear positive relationship with overall performance throughout the entire score range (Figure 5, top left). In these data, the higher the agreeableness-related score, the better. This is the case even with an average change in R of .045 after adding the quadratic predictor to the model. The first column in Table 14 shows that the multilevel quadratic coefficient was not statistically significant. The results for Agreeableness suggest that, using this scale, it is difficult to be too agreeable: From a “curve-fitting” perspective, the positive slope would not be forecasted to flatten out until well beyond the possible score range at a value equivalent to over 11 SDs above the predictor mean (Table 12). Figure 5 provides visual evidence that the form of the Agreeableness—performance relationship differed very slightly across criteria, although there is not enough difference to infer that the consequences for nonlinearity depend on these criteria as measured here.

Agreeableness—Overall Performance Moderation Analyses. Table 14 shows that neither of the moderation analyses for Agreeableness produced statistically significant results. As with Conscientiousness, the results are plotted in the final two components of Figure 5 for completeness. Although it appears that Agreeableness flattens

out lower in the scale for high complexity jobs (Table 21), the lack of statistical significance precludes any strong inference from these results.

Emotional Stability Results. Research question 3 addresses the emotional stability—performance relationship. Compiled results for the relevant analyses are shown in Tables 15, 16, and 12, and displayed graphically in Figure 6. Table 15 shows an unstandardized regression coefficient of .000 and a very small positive beta coefficient ($\beta = .004$) for the Emotional Stability predictor (change in $R = .035$). In this case, the unstandardized coefficient was actually very slightly negative. The appearance of the small positive beta coefficient here is an artifact of the weighted average procedure across validity studies, and should not be overinterpreted since there is no visual evidence of a nonlinear relationship between Emotional Stability and overall performance. However, the quadratic coefficient from the multilevel regression (Table 16, first column) was statistically significant. Given this situation, the simple slopes and graphical displays are particularly useful for interpretation, and suggest that the Emotional Stability—overall performance relationship can be described as unambiguously linear in spite of the finding of statistical significance. Figure 6 (top left) displays these findings. This is consistent with Table 12, which shows the projected bend point over 8 SDs above the mean at a centered value of 48.41, which in turn corresponds to a raw scale value around 75 (maximum possible is 38). Analyses for the alternative criteria showed that Emotional Stability exhibits positive relationships with each criterion (Figure 6; Table 12); however, those results are not definitive due to the lack of empirical differentiation

among criteria. Thus the general conclusion is that there are no expected performance declines in the high score range in these data.

Emotional Stability—Overall Performance Moderation Analyses. Table 16 shows that neither of the moderation analyses for Emotional Stability produced statistically significant results. Figure 6 (bottom left and right) contains plots of these equations, although strong caution is urged regarding interpretation. Fundamentally, there is a positive relationship between Emotional Stability and performance regardless of job complexity or the importance of adjustment for job performance.

Openness Results. Research question 4 addresses the openness—performance relationship. Results for the relevant analyses are shown in Tables 17, 18, and 12, and displayed graphically in Figure 7. For overall performance, a change in R of .046 is associated with a statistically significant quadratic coefficient in the multilevel regression (Table 18). Table 12 shows that the simple slopes for Openness are positive at low scores, but become increasingly negative starting about .75 SDs above the mean. The practical meaning in raw score units is abstract because the HPI does not use an operational openness scale, but these findings, along with the top left plot in Figure 7 suggest that those with standing above 1 SD could perform less optimally than those whose Openness standing is closer to the mean. Considering the relative magnitude of the simple slopes and the slight curvilinear trends in the regression line (Figure 7) and empirical loess curve (Figure 3, second row, right), the effects of this finding on job performance appear small.

The findings for Openness are very consistent in form across criteria, which is unsurprising given the substantial correlations between these criterion composites. Table 12 shows that the estimated bend points all occur between .5 to 1 standard deviations above the mean. Although any expected loss in performance compared with linear relationships is minimal, these findings indicate some departure from linearity associated with high standing on Openness.

Openness—Overall Performance Moderation Analyses. Table 18 contains multilevel regression equations for Openness, and shows that neither of the interaction effects for job complexity or the practical intelligence work style were statistically significant. Examination of the last two graphs in Figure 6 confirms the interpretation that there is no evidence for either of these moderators influencing the negative quadratic effect in the Openness—overall performance relationship.

Extraversion Results. Research question 5 addresses the extraversion—performance relationship. The focal results are shown in Tables 19, 20, and 12, and displayed graphically in Figure 8. The addition of the Extraversion quadratic term resulted in a change in R of .046 (Table 19). However, the multilevel quadratic coefficient was not statistically significant (Table 20), so any interpretation of a curvilinear effect should be done with caution. In the lower end of the score range, the slope is meaningfully positive (Table 12). However, the inflection point occurs at 1.15 SDs above the mean, with progressively higher Extraversion values associated with a declining trend in overall performance (Figure 8, top left). This regression line differs from the loess curve for Extraversion shown at the bottom of Figure 3. The loess curve

based on the scatterplot suggested no curvilinear effect: It is possible that the projection of the regression line in Figure 8 at the very high ends of the scale gives the impression of more of a curvilinear effect than the observed data support. Thus, if Extraversion is construed as a combination of Ambition and Sociability concepts, while it is possible that those with very high standing may underperform relative to those just above average, any curvilinear effect appears small. Figure 8 shows that the Extraversion predictor showed the same basic negative quadratic patterns for each criterion.

Extraversion—Overall Performance Moderation Analyses. Table 20 contains multilevel regression equations for Extraversion, and shows that neither of the interaction effects for job complexity or the social influence work style were statistically significant. The final two components of Figure 7 display these findings. As with the other predictors, these findings are reported for completeness, but strong caution is urged in interpretation given the non-significant results.

Further considering the concept of statistical significance. It is common for studies of curvilinearity to place weight on findings of statistically significant polynomial regression coefficients or changes in R or R^2 (Cohen et al., 2003). To provide some indication of this within validity studies, this study followed a strategy used by Coward and Sackett (1990) that tabulates the proportion of studies with statistically significant polynomial regression results. The results for each HPI predictor in reference to the overall performance criterion are shown in Table 22. In all analyses, the proportion of statistically significant quadratic coefficients was less than .1. These findings suggest that departure from linearity occurs only about as frequently as what could be expected by

chance alone. The analyses in Table 22 lead to fundamentally similar conclusions as the other analyses described above. The primary caveat in interpreting Table 22 is the consideration of factors contributing to power (Cohen, 1992) across the validity studies: sample size, effect size, and acceptable significance criteria. Sample size is particularly relevant given that it is the chief power-relevant characteristic varying across studies: the sample size in these studies ranged from 10 to 817.

Analyses for Recommended Scales

These analyses were conducted to examine the implications of nonlinearity for situations in which the predictor would be used operationally. Sample sizes for the analyses and regression equations are shown in Table 23. The simple slopes and bend points shown in Table 24 indicate that the findings from these analyses mirror those from the overall analyses (comparisons for bend points are found in Table 12). The slight exception is for the Openness scale, where the slight curvilinear effect from the overall analysis effectively disappeared: The estimated standardized bend point in the supplemental analysis was over 6 SDs above the mean, compared to just under 1 SD above the mean in the overall analysis. To provide a graphical comparison, Figure 8 contains the regression lines from the original “all available studies” analyses on the left side of the page and the regression lines from the “only recommended studies” analyses on the right side. Visual inspection of these graphs shows that each scale demonstrated the same general pattern of relationship when restricted to settings in which the scale was recommended for use.

SECTION 4: DISCUSSION

This study investigated the possibility that meaningful nonlinear trends occur in the relationships between personality predictors and occupational performance. The focus was on the Big Five personality framework, and the use of the Hogan Personality Inventory database allowed for the largest current investigation of these questions within the range of personality predictors and performance ratings observed in actual organizational settings. The use of a single personality instrument across over 100 validity studies provided an opportunity for comparison with the findings of previous studies for the Conscientiousness, Emotional Stability, and Openness predictors. Additionally, this study provided the first major tests for Agreeableness and Extraversion in reference to job performance. Results showed that, within validity studies, statistically significant quadratic effects did not occur frequently (Table 22). The typical sample size available for criterion-related validity studies may leave many studies of this nature underpowered for detecting nonlinearity, however, and this situation led to a strategy of pooling results across thousands of test-takers. These aggregated analyses showed that curvilinearity was unlikely to play a significant role in the relationships between these Big Five-oriented personality scales and job performance, in spite of theoretical rationale. The basic findings for each predictor are briefly summarized here.

Summary of Findings

The Conscientiousness quadratic coefficient in the multilevel regression equation was not statistically significant. Although Figure 4 showed that the form of the relationship was positive through most of the score range and leveling off at very high scores, the lack of statistical significance suggests the need for caution in interpreting any

graphed departure from linearity. The moderation analyses showed that job complexity, the importance of achievement orientation to the job, and the importance of conscientiousness to the job did not statistically significantly affect the Conscientiousness—performance relationship.

The Agreeableness results (Figure 5) exhibited no appreciable departure from linearity. That is, higher standing was usually associated with higher performance ratings. Further research in this area might identify samples in which Agreeableness scores are not negatively skewed, or focus on the Agreeableness—task performance relationship given the trend in this study, although the criterion breakouts are not definitive. Neither job complexity nor the rated importance of interpersonal orientation functioned as statistically significant moderators of the Agreeableness—performance relationship.

The trends for Emotional Stability (Figure 6) were linear and positive. This was the case even with the finding of a statically significant multilevel quadratic coefficient. When this finding was probed and graphed, there were no major expected performance declines or increases in the high ends of the predictor range, and any departure from linearity in the regression line carried negligible implications for performance. Moderation analyses showed that neither job complexity nor the rated importance of adjustment to the occupation yielded statistically significant effects.

Openness (Figure 7) produced the same fundamental negative quadratic pattern across criteria, and the multilevel quadratic coefficient was statistically significant. These results suggest that high standing on Openness may be associated with expected performance decline. However, when interpreted in light of the implications for job

performance, this slight curvilinear effect is unlikely influence differentiation among performers in the high end of the range. In terms of moderation, job complexity and the importance of practical intelligence to performance did not alter the form of the Openness—performance relationship.

Finally, the regression equation for Extraversion (Figure 8) suggested a slight negative quadratic pattern high in the score range, but the associated multilevel quadratic coefficient was not statistically significant. In addition, the loess curve for Extraversion (Figure 3) displayed no evidence of curvilinearity. The moderation analyses showed that neither job complexity nor the importance of social influence had a statistically significant effect on the point at which the Extraversion—performance relationship was estimated to change from positive to negative.

A set of supplemental analyses replicated these results by examining only settings in which each Big Five scale was recommended for operational use (Figure 9). Thus, the general conclusion is that none of the relationships between the personality predictors and overall job performance could be described as curvilinear enough to distort expectations about job performance. Although analyses of quadratic coefficients yielded statistical significance for Emotional Stability and Openness, when viewed in combination with the empirical loess curves (Figure 3) and simple slopes (Table 12), neither predictor showed a substantial curvilinear effect. In instances where the loess and regression graphs suggested any negative quadratic effects (for Conscientiousness and Openness), the curvilinearity could be characterized as leveling off (or “asymptotic”; Hough & Dilchert, 2010) within the score range. In this case, even if these curvilinear effects are real and

progressively higher personality scores are not associated with increased expected performance, the finding is that these high scores are also not associated with expected declines in performance.

Comparison with Previous Findings. As noted in the introduction, results for conscientiousness have been mixed in previous studies. The present findings for a non-significant quadratic coefficient across large samples is consistent with Robie and Ryan's (1999) study, which examined several conscientiousness measures in relation to overall performance ratings in five samples and found no evidence for departure from linearity. This study's loess and regression figures for Conscientiousness (Figures 3 and 4) suggested an asymptotic pattern similar to findings reported by LaHuis et al. (2005), who focused on overall performance ratings, Le et al.'s (2011) study 1, which focused on task, OCB, and CWB ratings, Whetzel et al. (2010), who focused on task performance ratings, Vasilopoulos et al. (2007), who focused on training performance, and Cucina and Vasilopoulos (2005), who focused on college FGPA. Nonetheless, the lack of statistical significance in this study across a large sample is a failure to replicate the statistically significant results reported by most of these authors. The reasons for the difference in findings is not immediately clear, although sampling error, the variety of criteria across these studies, and differences in the personality tests studied all may contribute.

This study's findings for Agreeableness are the first reported examinations of nonlinearity between a Big Five bandwidth predictor and job performance. Whetzel et al. (2010) examined two OPQ agreeableness-related scales, *Caring* and *Trusting*, in reference to task performance, and Cucina and Vasilopoulos (2005) examined the IPIP

Agreeableness scale in reference to freshman GPA. Neither of those studies found nonlinear agreeableness effects, similar to this study. Thus the emerging picture is that agreeableness scales do not exhibit meaningful departure from linearity in the settings in which studies have been conducted.

This study's results for a statistically significant emotional stability quadratic are consistent with Vasilopoulos et al. (2007) and Le et al. (2011), who reported statistically significant negative quadratic effects for emotional stability with training performance and task, OCB, and CWB, respectively. However, the graphed regression results reported by Vasilopoulos et al. and Le et al. show negative quadratic effects that are unlike the graphed results in this study, which indicated no curvilinearity. Thus, the substance of the current results may be similar to Cucina and Vasilopoulos's (2005) finding of no significant departure from linearity in the prediction of FGPA.

There are virtually no studies that have examined whether openness scales exhibit curvilinear relationships with job performance. This study provides the first major look, but can be compared to Whetzel et al.'s (2010) and Cucina and Vasilopoulos's (2005) findings. Whetzel et al. interpreted small (change in $R^2 < .05$) quadratic effects as evidence for linearity for their *Adaptable*, *Innovative*, *Conventional*, *Forward Thinking*, and *Variety Seeking* OPQ scales. In contrast, Cucina and Vasilopoulos found a negative quadratic for IPIP Openness in relation to FGPA. Importantly, Whetzel et al. noted that small nonlinear effects (change in $R^2 > .01$) did occur for their *Adaptable*, *Innovative*, and *Variety Seeking* scales. Similar to this study, even with the quadratic pattern, Whetzel et al. interpreted these findings as a general lack of evidence for meaningful curvilinearity

for openness predictors. Thus the balance of the evidence indicates slight curvilinear effects for openness, but the implications for performance appear to be minimal.

This study is also the first to provide a major examination of the form of the extraversion—performance relationship. Cucina and Vasilopoulos (2005) also reported a non-significant quadratic coefficient in the prediction of FGPA, and Whetzel et al. (2010) reported only linear effects (change in $R^2 < .01$) for the *Affiliative*, *Outgoing*, *Outspoken*, and *Socially Confident* scales in relation to task performance. The results from the current study are consistent with the available studies in this domain.

Moderation Analysis Comparison. In terms of the job complexity moderation analyses, Le et al. (2011) used a slightly different criterion measurement framework than the current study, used different personality measures, and used two different job complexity operationalizations (dichotomous high/low complexity in their Study 1 and O*NET's job zone in their Study 2). Thus these comparisons are more exploratory than definitive. In their first study, Le et al. found a statistically significant interaction between their Conscientiousness scale and task performance, such that the inflection point for low complexity jobs (.23 SDs) was much lower in the predictor scale than for high complexity jobs (2.33 SDs). That finding did not replicate in their second study using different measures, and notably, the same job zone complexity system used in this study. The significant job complexity moderator finding also did not emerge with the Conscientiousness—overall performance measure in this study.

Le et al. (2011) also found a significant emotional stability—complexity interaction in predicting the task performance criterion in their first study. Regression

lines for high and low complexity were in the form of a negative quadratic. This finding did not replicate in terms of statistical significance in their second study. Job complexity also did not have a significant moderating effect in the current study. Given the differences in the way variables were measured across studies and the general failure to replicate these findings, it could be said that the jury is still out with regard to strong conclusions in this domain (Schmidt, 2010).

When Does Departure From Linearity Matter?

It is useful to understand how personality scales relate to job performance indices from a basic science perspective. In practice, the question of the degree to which any finding of curvilinearity matters depends on how one wants to use the scores. Although this study found minimal evidence for curvilinearity, other studies have emphasized the possible consequences of curvilinearity for personality assessments (Converse & Oswald, 2012). The form of nonlinearity likely of greatest interest for selection professionals is a negative quadratic effect, in which progressively higher personality scale scores are associated with decreasing expected job performance. When used for administrative purposes, organizations can use personality test scores (a) to screen out applicants who do not meet a minimum threshold, (b) to rank test-takers in a top-down manner, or (c) in combination with scores from other assessments before making decisions.

Cut score strategies may be the most common administrative use of personality test scores, whereby those with low standing are screened out either for lack of fit or business necessity purposes. In the presence of curvilinear relationships, when cut scores are used the critical question becomes: At what point in the range of acceptable scores

could those who pass be expected to underperform relative to those who are screened out? That is, is the curvilinear regression line negatively sloped enough to indicate that those at a specified high standing on the personality characteristic could be expected to perform worse than those who scored below the cut score in the first place? The clear inference from this study is that such a result is unlikely to occur. For instance, if a cut score is set at -1 SD on the Openness predictor, the curvilinear effect is not substantial enough for this problem to occur, on average. Of course, the point at which this effect could occur depends on the location of the cut score in the predictor distribution. The higher the cut score, the greater the possibility for high scorers to perform worse than those screened out in the context of a negative quadratic regression line. Based on the current findings, these cut scores would need to be atypically high to result in very high scorers underperforming those screened out due to the quadratic effect. Further, this effect would likely be impossible for the Emotional Stability findings in this study. Although it may be possible for those with high standing on Openness to underperform relative to those failing to attain a cut score near the mean, the overall slope suggests that this would carry minimal performance implications. In addition, the analysis involving only studies in which openness-related scales were recommended for use yielded an effectively linear relationship between Openness and performance.

Organizations adopting a top-down rank order strategy with these scales should consider that this practice might result in slightly lower average performance than expected if the expectation is a robust linear relationship. The question of how much of a performance loss will depend on the point at which the relationship turns negative and

how steep the negative slope is in the high end of the score range. In this study, even in cases in which the bend point occurred relatively low on the scale (e.g., Openness—overall performance at .75 SDs) any declines in performance were still projected to be small given small slope coefficients. Nonetheless, it is possible that treating all personality—performance relationships as though they are linear when they may not be could be associated with lower than expected performance (Converse & Oswald, 2012).

It is unclear how frequently organizations use personality test scores to rank test-takers for purposes of making employment decisions. There are many ways that personality scale scores could be combined with other assessments, and Whetzel et al. (2010) note that some profile assessments implicitly or explicitly incorporate nonlinearity in scoring keys, perhaps without supporting empirical research. In this case, the results from this study may be useful as general priors for where cut scores could be established or how personality scores could be weighted; perhaps incorporating local data. The estimated bend points in this study are indicative of the HPI and the occupations represented in the analyses, but may not transport to other settings. The fundamental premise is that those wanting to estimate the utility of using personality assessments for administrative purposes must consider how the scores will be combined and used, and must also consider whether any potential nonlinearity could violate the assumptions inherent to a utility estimate.

Limitations, Additional Analyses, and Conclusions

This study contributes to the literature by examining personality scales relevant to the full Big Five model and potentially relevant moderators. The large samples and

coverage of occupations are strengths for the generalizability of the results. On the other hand, personality assessments are used in multiple ways in applied settings, and personnel decisions are usually not made solely on the basis of one predictor. When personality is assessed, multiple personality scales are usually administered and the data from each are combined in some way to contribute to a personnel decision. It is also the case that other non-personality assessments are often included in a procedure, and may be combined with personality assessment information within a stage or hurdle (DeCorte, Sackett, & Lievens, 2011, illustrate hypothetical examples). This situation makes it difficult to make concrete statements about the implications of departure from linearity in Big Five oriented measures outside of a bivariate framework, aside from the broad argument above that the findings of this study suggest that curvilinearity is unlikely to present a problem. It is also the case that scales exhibiting quadratic trends did not suggest large performance decrements.

Construct Validity. The emergent conclusion is that the complexity of constructs in the personality domain and differences how measures are designed and implemented (e.g., Hough et al., 1990; Hough & Ones, 2001) leads to difficulty in drawing any sweeping generalizations from this study about the implications for practitioners using other personality assessments. In terms of construct validity, the HPI scales used in this study are well researched and generally accepted among scientists and practitioners. However, the content of the Big Five scales derived from the HPI is likely to differ somewhat from other instruments, and the HPI was developed at least in part for use in workplace assessment, unlike some other personality measures. For instance, the HPI

Prudence scale correlated with NEO Conscientiousness and Agreeableness at nearly equal magnitudes in a sample from the Baltimore Longitudinal Study of Aging ($n = 124$; Costa & McCrae, 1995). Thus Hough et al.'s finding that personality scales ostensibly representing the same-labeled domain may not be empirically interchangeable, even when accounting for measurement error, is likely as true today as it was in 1990. Nonetheless, the fact that the same assessment was used for all validity studies examined here is considered a strength for interpretation. This fact makes it clear that estimated bend points for the analyses may not generalize to other instruments.

One further construct-related issue is the focus on the conceptual and empirical Big Five bandwidth of the personality predictors. Some scholars have long argued that the breadth of the Big Five can easily obscure patterns of subscale correlations with other variables, such as job performance indices (Hough, 1992). Recent studies have shown that facet level predictors (i.e., sub-Big Five) often correlate differently with various criteria (e.g., Dudley et al.'s [2006] examination of conscientiousness). In the current study, sub-Big Five facet scales were available for openness (HPI's Inquisitive and Learning Approach) and extraversion (HPI's Ambition and Sociability). Additional analyses were conducted to examine whether these scales exhibited the same trends as their broader composites. Each facet was examined in reference to overall performance for comparison purposes, using the same approach as the Big Five analyses reported above.

Table 25 contains the regression results for these scales, and Figure 10 displays the graphs for comparison. For the openness domain, the major finding was that the two

subscales exhibited similar asymptotic negative quadratic patterns. For the extraversion domain, curvilinearity was more prevalent for the Sociability scale than the Ambition scale. The trends were quite different for these two scales: Sociability suggested a negative quadratic effect, which could be explained by a tendency for those who socialize frequently at work to underperform relative to somewhat less sociable employees. In contrast, Ambition exhibited a slight positive quadratic effect, where higher scores were associated with increased returns to performance. Thus the broad finding for these scales was that the facets of openness exhibited similar patterns and facets of extraversion exhibited different patterns, in line with reasoning that more detailed levels of the personality hierarchy may yield differing patterns within a broader Big Five concept (Hough & Dilchert, 2010). Vasilopoulos et al. (2007) also reported different curvilinear patterns for subscales of conscientiousness (dependability and achievement) and emotional stability (stress resistance and frustration tolerance) available in their study. One caveat is that this “facet” structure for openness and extraversion could be considered idiosyncratic to the HPI, and it is possible that Ambition could conceptually be situated at a hierarchical breadth more akin to “compound traits” such as Integrity or Customer Service Orientation (Judge & Kammeyer-Mueller, 2012). In fact, Hogan Assessment Systems would probably not consider these scales as “facets” in the same way that Costa and McCrae (1995) use the term. Recall that the 7 HPI scales are comprised of 41 homogeneous item clusters that may fall more into the “facet” category.

Additionally, the sampling of these validity studies could be described as more convenient than systematic. To be included in the database, organizations would need to

have been interested in using personality assessments and willing to participate in validation research, perhaps at their own expense. On the other hand, this situation is common for field research synthesis, and the coverage of industries and occupations is broad. Thus the sampling is comparable in scope to many meta-analyses relying on field studies.

An additional consideration is that studies of this nature can provide trends and associations between personality test scores and performance ratings, but they tell us fairly little about the mechanisms or specific behaviors of those scoring at any given point on each personality scale's score range. For instance, why might those scoring very high on conscientiousness scales not receive increasingly higher performance ratings, on average? It is possible that these individuals behave in rigid or compulsively self-disciplined ways as has been previously theorized (Murphy, 1996; Widiger et al., 2002), but little attention has been paid to whether these specific behaviors are actually exhibited by high scorers. As another example, do those with high standing on extraversion inventories display socially dominant or excessively bold behavior? Numerous questions could be identified for each personality characteristic of interest. Research examining the actual behaviors defining test score ranges could be useful.

Links to other research literatures outside of I-O psychology may also be fruitful in this line of research. For instance, there has been recent movement by clinical researchers to understand whether abnormal or extreme personality-related behaviors can be represented by trait continua, rather than discrete categories of non-normal range personality (Clark, 2007; Krueger & Tackett, 2003; Markon et al., 2005; Widiger et al.,

2002; Widiger & Trull, 2007). That is, description of non-normal-range personality disorder can be both conceptually and empirically based on the same dimensional models as description of normal personality; namely, the Big Five. This line of reasoning may be useful for the fundamental question about why curvilinearity could matter in workplace settings: Why might high scores be associated with suboptimal performance? Much clinical work has focused on understanding the content of maladaptive personality-related behavior, particularly for those with very high standing on certain personality traits. The clinical/I-O link represents an appealing approach in this domain, but the literatures have remained separate so far: From an I-O perspective, the likely reason is that much I-O research is focused on practical intervention that could be applied in organizations and would fare well against scrutiny based on various legal frameworks (e.g., Americans with Disabilities Act compliance). However, when viewed from a basic science perspective, the concern with implications for personnel assessment in operational settings may be minimized. The major point is that the separation of clinical and I-O personality literatures may serve to obscure the ends of the Big Five continua because measures intended for use in one domain (i.e., clinical practice or personnel assessment) are not intended for the other, and this is done purposefully (Krueger, Derringer, Markon, Watson, & Skodol, 2011; MacLane & Walmsley, 2010). Nonetheless, exploration of this link in future research could be useful for explaining why high scores in the normal range of personality scales could be associated with performance declines.

Criterion Focus. This study relied primarily on an index of overall performance. Four additional criterion domains were examined, but all were measured using a common

method (supervisory ratings), and there was little evidence for empirical differentiation between domains given positive manifold and low reliability for some domains.

Emphasis on overall performance may not be a problem in terms of fidelity to practice since this represents a typical state of affairs in applied research. However, these analyses were conducted from the perspective that it may be informative to at least consider the conceptual substance of the performance domains of interest when interpreting results of nonlinearity analyses (Cucina & Martin, 2013). The results showed that the performance domains made little difference, perhaps due to their measurement properties. It is possible that a performance measurement program that incorporates multiple measurement methods and targets multiple performance domains (e.g., Campbell, McHenry, & Wise, 1990) could be very informative for this line of research.

The Meaning of Moderation. Turning to the moderation analyses, in spite of the rationale that job complexity and the judged importance of personality characteristics for job performance could influence the personality—performance relationship, none of the analyses produced statistically significant results. Thus the effects of job complexity in this study are not as dramatic as the moderation findings reported, but in some cases not replicated, by Le et al. (2011).

An additional consideration is that job analysis ratings of the importance of given personality traits for performance may implicitly take into account curvilinearity, but not in a way that is evident in a set of importance ratings. Importance ratings may not provide any indication of the “ideal point” for a trait to operate in context – a rater may believe that a trait is highly important but also believe that it is optimal to behave in a way that

displays moderate standing on the trait, rather than “more is better” (e.g., Kuncel & Tellegen, 2009 provide the example of talkativeness). This could be the case if raters tend to provide importance ratings that are a reflection of their trait standing or focus on an idealized profile of traits to match job characteristics (Aguinis, Mazurkiewicz, & Heggestad, 2009; Cucina, Vasilopoulos, & Sehgal, 2005). Consider importance ratings for agreeableness: When incumbents provide ratings for low complexity jobs, they may decide that getting along with customers is important and provide a high rating (i.e., a 4 or 5 on a 5-point scale). In this case the rater may implicitly consider a linear monotonic relationship between agreeableness and performance related to getting along with others. In contrast, incumbents in high complexity managerial positions may decide that while some degree of agreeableness is critical, being too agreeable may undermine a manager’s authority in other settings. These incumbents may rate agreeableness very high in importance but simultaneously believe that moderate standing on the trait is optimal compared to very high standing.

Thus, the moderator analyses herein are interpreted more as an initial look into these questions. The results suggest possible trends or considerations rather than a definitive test. As described above, a major caveat is that occupation-level data were drawn from O*NET and matched by SOC code, rather than by gathering occupation information specific to the validity studies in question. Ultimately, practitioners could consider consequences of personality test use in specific settings given information about how assessment scores might be used. Researchers could generate hypotheses on the basis of these results and those of Le et al. (2011) in planning future definitive testing.

Further research that collects this type of data in the same environment in which predictor and criterion data are collected could be very beneficial.

Curvilinearity in Context. Finally, as with many studies examining bivariate correlations between personality predictors and job performance ratings, the slopes of these relationships could be regarded as small (Morgeson et al., 2007). However, none of these coefficients were corrected for statistical artifacts such as range restriction or criterion unreliability that may obscure the potential utility of using personality assessments in operational settings (Barrick & Mount, 1991; Ones et al., 2007). The absolute magnitude of the R^2 coefficients from the hierarchical regressions is small and consistent with coefficients in the personality—job performance literature that are uncorrected for statistical artifacts such as range restriction and unreliability. The discussion herein focuses on the form of the observed relationship, as other studies have examined linear slopes with emphasis on correction for statistical artifacts (see examples in Table 1), as well as implications of using multiple personality scales and compound traits for predicting performance (Barrick et al., 2001; Hogan & Holland, 2003; Hough & Johnson, 2013; Ones et al., 2007; Ones & Viswesvaran, 2001). The addition of the quadratic predictors to the regression models indicated slight incremental validity for predicting performance, consistent with similar studies (Le et al., 2011). It is true that a primary argument for the use of personality scales is their relevance for predicting performance, but it is also the case that the classic bivariate predictive validity model may not be well suited for understanding the power of personality predictors (e.g.,

Campbell, 1990). In any case, the magnitude of the slope is a relevant component of an argument about the consequences of departure from linearity.

Table 1. Total Sample Job Zone and Job Family Distributions

	Frequency	Percent
Job Zone		
1 = Little or no preparation needed	742	5.7
2 = Some preparation needed	6,414	49.1
3 = Medium preparation needed	2,136	16.3
4 = Considerable preparation needed	3,269	25.0
5 = Extensive preparation needed	229	1.8
Missing	274	2.1
Job Family		
Administrative & Clerical	792	6.1
Managers & Executives	3,048	23.3
Operations & Trades	3,427	26.2
Professionals	1,098	8.4
Sales & Customer Support	1,823	14.0
Service & Support	1,777	13.6
Technicians & Specialists	1,100	8.4

Note. Job Zone descriptions are provided as quick reference; more detail on the job zone classification can be found in Oswald et al. (1999) and the DOL O*NET website: <http://online.onetcenter.org/help/online/zones>.

Table 2. Demographic Distribution of Total Sample

	Frequency	Percent
Gender		
Male	7,583	58%
Female	3,435	26.3%
Missing	2,047	15.7%
Ethnicity		
Black	1,409	10.8%
Hispanic	878	6.7%
Asian	347	2.7%
American Indian	92	.7%
White or Caucasian	6,877	52.6%
Native Hawaiian or Pacific Islander	33	.3%
Other	107	.8%
Missing, Not Indicated, or Declined	3,311	25.3%

Table 3. Sample Age and Tenure Descriptive Statistics

	# Respondents	Minimum	Maximum	Mean	SD
Age	8,171	16	75	37.97	10.73
Years in Position	5,398	0	39.41	3.99	5.61

Table 4. Descriptive Statistics for the Predictor Variables

	N	Minimum	Maximum	Overall Mean	Overall SD	Skewness
Conscientiousness	13,056	1	31	20.70	4.35	-.387
Agreeableness	12,004	1	22	19.43	2.45	-1.764
Emotional Stability	13,061	3	38	27.27	6.33	-.745
Openness	12,046	-5.21	4.73	0.00	1.59	-.174
Extraversion	13,059	-6.47	4.49	0.00	1.52	-.485

Note. Descriptive information for all scales except Extraversion and Openness is based on raw score scaling. Extraversion and Openness are unit-weighted composites of their respective sets of two facets, and their scaling is based on sums of two standardized variables.

Table 5. Descriptive Statistics for Competency Composites

	N	Minimum	Maximum	Overall Mean	Overall SD	Skewness
Intrapersonal Performance	9,973	-3.37	2.30	.002	.791	-.342
Interpersonal Performance	9,493	-4.01	2.33	.003	.833	-.349
Leadership Performance	6,014	-3.68	3.45	.001	.909	-.164
Work Skill Performance	8,203	-4.68	3.85	.004	.884	-.321
Overall Performance	12,219	-4.35	3.19	.000	1.00	-.299

Table 6. Number of Competencies Per Validity Study Contributing to Composites

	Minimum	Maximum	Mean	SD
All Competencies	1	46	10.52	9.25
Intrapersonal Performance	1	16	5.26	4.59
Interpersonal Performance	1	11	2.32	2.15
Leadership Performance	1	11	1.14	1.94
Work Skill Performance	1	10	1.55	1.85

Table 7. Correlations Among Predictor Scales and Performance Variables

	1	2	3	4	5	6	7	8	9
1. Conscientiousness									
2. Agreeableness	.352								
3. Emotional Stability	.495	.410							
4. Openness	.083	.169	.229						
5. Extraversion	-.033	.297	.252	.465					
6. Intrapersonal Performance	.092	.064	.098	.025	.043				
7. Interpersonal Performance	.102	.117	.117	.014	.044	.747			
8. Leadership Performance	.054	.049	.072	.032	.073	.667	.669		
9. Work Skill Performance	.071	.036	.070	.041	.045	.660	.606	.608	
10. Overall Performance	.084	.071	.104	.028	.057	.796	.803	.749	.692

Note. Among predictors, N range = 13,058 – 11,999. Among predictors and criteria, N range = 12,215 – 5,866.

Table 8. Reliability Estimates for Performance Composites

Performance Domain	Mean Correlation	Mean Number Competencies Rated	Spearman-Brown Estimate
Within Domain (Convergent)			
Intrapersonal	.46	5.26	.82
Interpersonal	.47	2.32	.67
Leadership	.45	1.14	.48
Work Skill	.40	1.55	.51
All Competencies	.43	10.52	.89
Between Domain (Divergent)			
Intrapersonal—Other	.43	--	--
Interpersonal—Other	.44	--	--
Leadership—Other	.40	--	--
Work Skill—Other	.41	--	--

Note. “Other” indicates performance ratings for dimensions categorized in a different domain than the focal domain for the analysis.

Table 9. Correlations Among O*NET Variables

	Mean	SD	Minimum	Maximum	Median	Number of Component Descriptors	1	2	3	4	5	6	7
1 Achievement Orientation	3.81	.49	2.91	4.69	3.89	3	(.94)						
2 Social Influence	3.62	.66	2.21	4.84	3.57	1	.81	(-)					
3 Interpersonal Orientation	3.76	.45	2.90	4.69	3.82	3	.51	.60	(.88)				
4 Adjustment	4.03	.36	3.33	4.76	4.09	3	.68	.69	.80	(.87)			
5 Conscientiousness	4.31	.31	3.31	4.87	4.39	3	.71	.60	.69	.76	(.77)		
6 Independence	3.99	.28	3.10	4.63	3.96	1	.34	.32	.42	.46	.40	(-)	
7 Practical Intelligence	3.55	.40	2.41	4.30	3.60	2	.69	.82	.50	.64	.52	.43	(.79)

Note. SD = standard deviation. N = 123. Cronbach's alpha coefficients are shown in parentheses along the diagonal.

Table 10. Weighted Mean Regression Coefficients For Conscientiousness with Each Performance Criterion

Predictor	B	β	R	R ²
Overall Job Performance (n = 12,212, k = 123)

Work Skill Performance (n = 8,199, k = 65)				
Step 1			.092	.014
Constant	.004			
Extraversion Linear	.025	.045		
Step 2			.130	.025
Constant	.008			
Extraversion Linear	.022	.040		
Extraversion Quadratic	-.003	-.009		

Table 20. Multilevel Regression Results for Extraversion and Overall Job Performance Examining the Job Complexity and Work Style Moderators

Predictor	No Moderator Examined		Moderator Variable			
	B	Pseudo R ²	Job Complexity		Social Influence Work Style	
			B	Pseudo R ²	B	Pseudo R ²
Extraversion						
Step 1				.000		-.001
Intercept			.006		.007	
Moderator			.003		.008	
Step 2		.003		.007		.004
Intercept	.005		.006		.006	
Moderator	--		.003		.009	
Extraversion Linear	.037*		.039*		.036*	
Step 3		.006		.006		.005
Intercept	.018		.017		.019	
Moderator	--		-.002		.005	
Extraversion Linear	.033*		.035*		.033*	
Extraversion Quadratic	-.006		-.006		-.006	
Step 4				.006		.005
Intercept			.015		.017	
Moderator			-.007		-.001	
Extraversion Linear			.040		.036	
Extraversion Quadratic			-.005		-.005	
Extraversion Linear * Moderator			.012		.013	
Extraversion Quadratic * Moderator			.003		.004	

Note. Criterion for each analysis is overall job performance. B = unstandardized regression coefficient (fixed effect). * = p < .05.

Table 21. Potential Moderating Effects for Each Personality—Overall Job Performance Relationship

Predictor—Criterion—Moderator Combination	Regression Coefficients			Standardized Inflection Point
	Intercept (B0)	Linear (B1)	Quadratic (B2)	
Conscientiousness—OJP				
Low Complexity	.018	.026	-.001	3.363
Mean Complexity	.021	.014	-.001	1.725
High Complexity	.024	.002	-.001	.285
Conscientiousness—OJP				
Low Achievement Orientation Importance	.020	.023	-.001	2.394
Mean Achievement Orientation Importance	.022	.018	-.001	2.150
High Achievement Orientation Importance	.025	.013	-.001	1.823
Conscientiousness—OJP				
Low Conscientiousness Importance	.020	.022	-.001	2.270
Mean Conscientiousness Importance	.022	.019	-.001	2.312
High Conscientiousness Importance	.023	.015	-.001	2.374
Agreeableness—OJP				
Low Complexity	.002	.035	.001	-7.396
Mean Complexity	.013	.026	-.001	5.330
High Complexity	.024	.016	-.003	1.110
Agreeableness—OJP				
Low Interpersonal Orientation Importance	-.015	.040	.001	-6.953
Mean Interpersonal Orientation Importance	.007	.030	.000	14.394
High Interpersonal Orientation Importance	.030	.019	-.002	1.938
Emotional Stability—OJP				
Low Complexity	-.008	.024	.000	-6.377
Mean Complexity	.001	.015	.000	-10.111
High Complexity	.010	.007	-.000	12.079

Predictor—Criterion—Moderator Combination	Regression Coefficients			Standardized Inflection Point
	Intercept (B0)	Linear (B1)	Quadratic (B2)	
Emotional Stability—OJP				
Low Adjustment Importance	-.024	.025	.001	-3.571
Mean Adjustment Importance	-.005	.019	.000	-6.031
High Adjustment Importance	.014	.014	-.000	29.878
Openness—OJP				
Low Complexity	.023	.016	-.006	.798
Mean Complexity	.030	.020	-.009	.680
High Complexity	.036	.024	-.012	.619
Openness—OJP				
Low Practical Intelligence Importance	.025	.015	-.009	.488
Mean Practical Intelligence Importance	.031	.016	-.008	.602
High Practical Intelligence Importance	.037	.017	-.007	.759
Extraversion—OJP				
Low Complexity	.021	.028	-.007	1.267
Mean Complexity	.015	.040	-.005	2.932
High Complexity	.008	.052	-.002	9.887
Extraversion—OJP				
Low Social Influence Importance	.019	.022	-.009	.813
Mean Social Influence Importance	.017	.036	-.005	2.323
High Social Influence Importance	.016	.049	-.001	14.790

Note. OJP = Overall job performance. Low Moderator = -1 SD. High Moderator = +1 SD.

Table 22. Number of Statistically Significant Quadratic Coefficients in Individual Study Polynomial Regressions

Predictor and Criterion	k	Number $p \leq .05$	Proportion $p \leq .05$
Overall Job Performance			
Conscientiousness	123	8	.065
Agreeableness	114	8	.070
Emotional Stability	123	1	.008
Openness	114	9	.079
Extraversion	123	10	.081

Note. Statistical significance, or $p < .05$, refers to whether the R^2 change statistic or quadratic regression coefficient entered in step 2 of the hierarchical regression met a typical threshold for statistical significance. The count includes both negative and positive quadratic coefficients.

Table 23. Weighted Mean Regression Results For Studies in Which Big Five Scale Was Recommended for Use

Criterion and Predictor	B	β	R	R ²
Overall Job Performance (n = 83, k = 7,571)				
Step 1			.131	.027
Constant	.005			
Conscientiousness Linear	.026	.103		
Step 2			.169	.042
Constant	.026			
Conscientiousness Linear	.025	.101		
Conscientiousness Quadratic	-.002	-.029		
Overall Job Performance (n = 62, k = 5,398)				
Step 1			.133	.028
Constant	.006			
Agreeableness Linear	.041	.107		
Step 2			.176	.042

Appendix A. Sampling of Meta-Analytic Criterion-Related Validity Estimates for Big Five Personality Predictors

Criterion Domain and Study	N Range	Big Five Personality Factor				
		Conscientiousness	Agreeableness	Emotional Stability	Extraversion	Openness to Experience
Overall Job Performance						
Barrick & Mount (1991) ¹	9,454–12,893	.22	.07	.08	.13	.04
Tett, Jackson, & Rothstein (1991) ³	280–2,302	.18	.33	.22	.16	.27
Mount, Barrick, & Stewart (1998) ¹	1,507–1,586	.23	.18	.16	.12	.14
Hurtz & Donovan (2000) ²	4,881–7,342	.22	.10	.14	.09	.05
Task Performance Criterion						
Hurtz & Donovan (2000) ²	1,176–2,197	.15	.07	.13	.06	-.01
Organizational Citizenship Behavior						
Hurtz & Donovan (2000) ^{2,4}	2,514–4,301	.17	.13	.15	.08	.03
Chiaburu et al. (2011) ³	6,700–14,355	.22	.17	.15	.11	.17
Counterproductive Work Behavior						
Berry, Ones, & Sackett (2007) ^{3,5}	1,772–3,458	-.32	-.39	-.24	-.03	-.07
Salgado (2002) ²	1,299–6,276	-.26	-.20	-.06	.01	.14

Note. Adapted from Sackett and Walmsley (2012). Meta-analytic validity coefficients are corrected for sampling error. All studies presented correlations for all of the Big Five dimensions. ¹ Indicates corrections for unreliability in the criterion.

² Indicates corrections for unreliability in the criterion and range restriction.

³ Indicates corrections for unreliability in predictor and criterion.

⁴ Validity coefficients for Hurtz and Donovan's (2000) Organizational Citizenship Behavior criterion are weighted means across their *Interpersonal Facilitation* and *Job Dedication* criteria.

⁵ Validity coefficients for Berry, Ones, and Sackett's (2007) Counterproductive Work Behavior criterion are weighted means across their *Interpersonal Deviance* and *Organizational Deviance* criteria.
