Acknowledgements

I would like to take this opportunity to acknowledge all who have helped, assisted and supported me in the completion of this thesis.

I would like to primarily thank my adviser Dr. Ona Egbue for her precious guidance and support in this research over the past two years.

I would also like to thank my thesis examining committee, Dr. Ryan Rosandich and Dr. Wenqing Zhang for their time and insightful comments and recommendations.

I would like to acknowledge the Chancellor's Fellowship I received from the QMA fund at the University of Minnesota Duluth. I would also like to thank Dr. Hongyi Chen, who have supported me in getting this fellowship.

I am very grateful of my parents, Reza Hosseinpour and Ziba Hedayati and my brother Nima for their endless support and love. I am also grateful of all my friends and fellow students in the MIE department for their friendship and support.

I would like to dedicate this thesis to my husband, Hossein Tohidi, who has always been there for me, supporting and encouraging me, especially in the past two years. He has been my main motivation in starting and accomplishing my Masters' degree, specifically this thesis.

Abstract

The increase in electric vehicle (EV) demand and the associated electricity load on the power network have made researchers to start working on managing and controlling EVs' connection time to the electricity grid. Vehicle to grid concept was introduced to enable EVs to connect to the grid and discharge their extra electricity to the network so that the utility company could use it for regulation purposes. In this thesis, offline and online scheduling optimization models are developed for EV charging and discharging. The objective of the optimization models is to maximize the satisfaction of EV customers. Customer satisfaction is incorporated using different factors through multiple scenarios. In the offline model, all EVs and grid information are known for the V2G management to decide the scheduling for EVs. Mixed integer linear programming is used to solve the offline model. The result of the offline model is the optimum solution the scheduling problem could get. On the other hand in the online model, which is a more realistic case, EVs arrival and departure times and their parameters are not identified in advance. For this model, rolling horizon optimization is used in the online scheduling algorithm. Applying rolling horizon enables the author to get the optimal solution for the online model. Mixed integer linear programming is linked with a MATLAB algorithm to solve the online scheduling model. A numerical example, including a large number of EVs in a parking lot is generated to test the efficacy of both proposed models.

CHAPTER 1

INTRODUCTION

1.1 Thesis Overview

In recent years, governments and societies have called for more sustainable practices to protect the environment. A major source of concern is the effect of fossil fuel use on the environment. Oil supplies are not infinite and are declining. Environmental and health issues together with air pollution, which are mainly brought about by fossil fuel consumption are causing people to seek new technologies for transportation. Almost one-half of the United States (U.S.) carbon dioxide emissions are generated from transportation, and almost one-half of all petroleum used in the U.S. are used for motor gasoline (Heutel & Muehlegger, 2010). Moreover, according to the U.S. Department of Energy's alternative fuels data center (2015), about 33% of the U.S. petroleum consumption comes from foreign countries. DOE also states that transportation accounts for three-quarters of total U.S. petroleum consumption.

Green transportation or sustainable transportation means “Transportation that meets the current transport and mobility needs without compromising the ability of future generations to meet these needs” (Black, 2004). Some of the main developments taking place today which are aligned with the green transportation are alternative energy sources such as hydrogen, bio-fuels, and natural gas to power internal combustion engines (ICE),

accompanied by new transportation technology such as electric vehicles (EV) (Hosseinpour & Egbue, 2015)

In an internal combustion engine, gasoline or diesel fuel generates mechanical energy to run the vehicle (Richardson, 2013). Alternative Fuel Vehicle (AFV) is the term used for vehicles running on at least one substitute fuel to petroleum such as; electricity, bio-fuel, and compressed natural gas (Egbue & Long, 2012). A major problem of using alternative fuels is that they have a lower energy density than gasoline, which ends up having a shorter range (Shukla, Pekny, & Venkatasubramanian, 2011). The number of EVs are increasing because of their potentiality in decreasing CO₂ emissions, and transportation costs (Egbue & Hosseinpour, 2014). Only in 2014, 570,475 EVs are sold in United States (Electric Vehicles Transportation Association, 2015).

A rise in the number of EVs mean more electricity draw on the power grid, which would cause blackouts in the network. By the use of Vehicle to Grid (V2G) system, and EVs participation in this system, power could be discharged back to the electricity network. This technology helps in regulation of demand, and makes up for the higher EV prices by providing the opportunity for owners to sell the electricity back to the utility company. Essentially, charging and discharging schedules of EVs in a V2G system will need to be controlled and managed. In this study, optimum offline and online scheduling of EVs are developed to maximize EV owners' satisfaction from participating in a V2G system.

1.2 Objectives of Thesis

In this thesis, the first objective is to develop the mathematical modeling for optimized schedule of EV charging and discharging in a V2G system to maximize customer satisfaction. Second, by considering different scenarios, it is intended to examine the effect of each factor on customer satisfaction, for instance; how does considering unfulfilled electricity requests affect EV owner's satisfaction?, or how does considering a limited number of battery switching have effect on increasing customer satisfaction?

As the next objective, developing both offline and online scheduling will help the author to compare the results of these two models and make appropriate conclusions. In the offline model, all the electricity network data and EV related information are known in advance. Thus, the model schedules charging and discharging for EVs based on all these information. But in the online model, the electricity grid information is the only data which is known beforehand, and EV specifications are not identified until they enter the system. Therefore, the model schedules charging and discharging for an EV, without knowing any information about other EVs in the system.

The next objective of the model is to test the efficacy of the proposed online methodology to find out how different the results of online model are from the offline model. In the literature, heuristics/meta heuristics algorithms are mostly used for dynamic scheduling problems, in which the results are not guaranteed to be globally optimum. But in this thesis, rolling horizon optimization approach is used which results in a global optimum solution. It is expected that the results of online model be very close to the offline model, which has the optimal solution.

1.3 Thesis Outline

This thesis is organized into five chapters. The remainder of this thesis is as follows:

In *Chapter 2*, a literature review is provided. This chapter includes information regarding EVs background and their different types, introduction to V2G system, offline scheduling literature, online scheduling studies, and rolling horizon technique.

In *Chapter 3*, the research methodology is discussed. The developed mathematical models for both offline and online scheduling, along with the online scheduling algorithm are presented in this chapter.

In *Chapter 4*, results of this study are provided. Offline and online model results, as well as the comparison of the results of these two models are discussed in this chapter.

Chapter 5, includes the concluding remarks and future research directions.

CHAPTER 2

LITERATURE REVIEW

2.1 Electric Vehicles

Electric vehicles (EVs) are types of vehicles powered by electricity. There are different types of electric vehicles: hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), and battery electric vehicles (BEVs). HEVs have higher fuel economy, since they include both an internal combustion engine and a rechargeable battery (Heutel & Muehlegger, 2010). They have a mixture of the best attributes including: being environmental friendly, having fuel efficiency, and meeting economical needs of consumers without having the range problems of EVs (Graham, 2001). In HEVs, the battery is recharged by a second engine which most often is a combustion engine. Thus, they do not need to be connected to the electricity grid in order to charge. Looking at HEV's history of development, it can be seen that they were successful in the market. There has been an increase in HEVs' share of U.S. market from 0.4% of all retail sales in May 2004 to 3.6% in July 2009 (Heutel & Muehlegger, 2010).

The PHEV is another type of electric vehicle. PHEVs can be refueled from both the electricity grid, or at a gas station. Their battery capacity is larger than that of HEVs, which is the main reason of their higher cost compared to HEVs (Grahm & Söder, 2011).

PHEVs' battery can power the vehicle for distances between 20 and 60 mile (Sovacool & Hirsh, 2009). According to the Minnesota Pollution Control Agency, PHEVs would drop CO emissions around 60–70% in comparison to internal combustion engines (ICEs). Furthermore, PHEVs reduce carbon dioxide emissions by 59% to 66%, nitrogen oxides from 48% to 80%, and particulate matter from 66% to 76% (Sovacool & Hirsh, 2009). A great example of PHEVs in the market is Chevy Volt which its 2015 model sells for almost \$34,000 (Chevrolet, 2015).

BEVs are another type of electric vehicles powered solely by a rechargeable battery. Their battery is usually larger than PHEVs' which can run for a longer range, and having a full charge, BEVs can run for up to 100 miles (Egbue & Long, 2012). Nissan Leaf is one of BEV models in the market. The 2015 model of Nissan Leaf sells for almost \$36,000 (Nissan, 2015).

One of the main issues for resistance to purchasing an EV is range limitations (Tsang, Pedersen, Wooding, & Potoglou, 2012). People are used to internal combustion engines, which can run for almost 600-700 km (370-430 miles) before refueling. Customers mostly fuel their ICEs once a week, but EVs' battery may need recharging once a day (Grahm & Söder, 2011). Based on Denholm & Short (2006), in the U.S., almost 50% of people drive less than 42 km per day, and 90% less than 150 km (93.2 miles). Based on the information given above, BEV would almost cover the 100 miles needed by American drivers. Since PHEVs run on both electricity and gasoline, they have a higher range of 379 miles (Berman, 2011). Therefore, both BEVs and PHEVs can meet the range needs and there should not be a big range concern among people.

In recent years, EVs' market has increased. In 2011, the U.S. government set a goal of having one million EVs on the roads by 2015 (U.S. Department of Energy, 2011b). Figure 1 shows the overall growth trend of plug-in sales in each year. As can be seen in the figure, since 2011 and after the one million goal was set, plug-in vehicles sales in the U.S. has been increased. The number of plug-in sales for 2015 is by month of April.

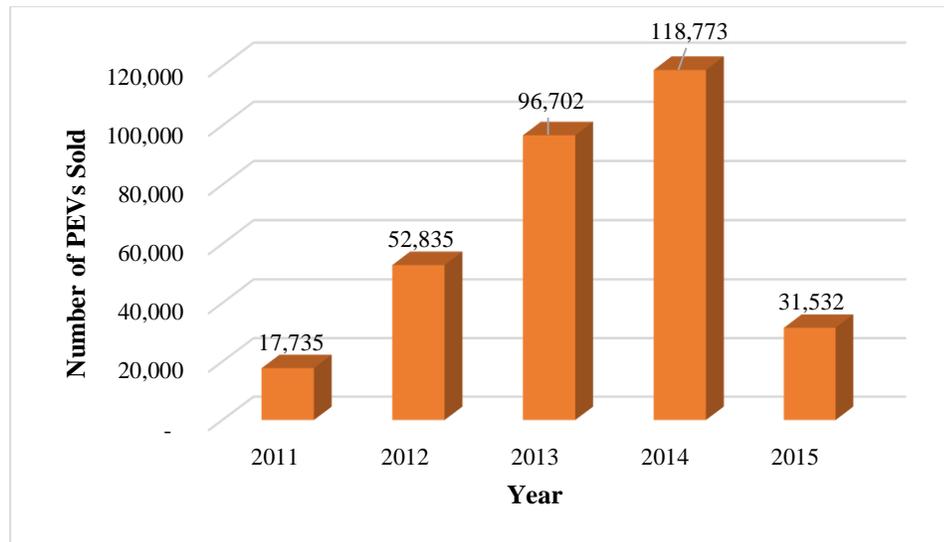

Figure 1. Overall growth- total yearly plug-in sales (Electric Vehicles Transportation Association, 2015)

Figure 2 also shows plug-in EV sales market trend from Jan 2011 to Jan 2015.

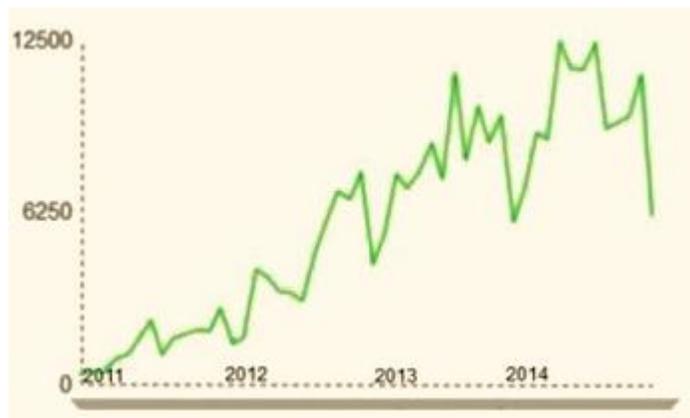

Figure 2. Plug-in sales market trend (Electric Vehicles Transportation Association, 2015)

In 2014, 570,475 EVs were sold in the United States (Electric Vehicles Transportation Association, 2015), including hybrid electric vehicles, plug-in hybrid electric vehicles, and battery electric vehicles.

As the number of EVs increase, they need more electricity from the electricity grid to be charged. Owners will charge their EVs at homes as well as at public charging infrastructures. This will cause a massive upsurge in the electricity network. According to Ipakchi & Albuyeh (2009), charging an electric vehicle means doubling the average electricity load. This higher load of electricity, needs to be addressed by developing infrastructure and technologies to mitigate such occurrences.

2.2 Vehicle to Grid System

One way to deal with the increase in EV demand, the intensified peak loads, and to keep grid stable is the application of vehicle to grid (V2G) (Egbue & Hosseinpour, 2014). In a V2G system, EVs will be used to manage the electricity load by serving as energy storage units and store energy from the grid during off-peak hours, and will discharge and deliver electricity back to the grid during peak hours (Egbue & Hosseinpour, 2014). Put in other words, EVs can provide ancillary services like regulation, and match generation to load if their charging and discharging are scheduled very carefully (Lin, Leung, & Li, 2013).

The advantage of V2G for transportation is to decrease petroleum consumption, enhance the economy and national security, and provide a better environment (Sovacool & Hirsh, 2009). Also EV owners can lower their costs of utilizing their EVs by participating

in the V2G system. The revenue an EV owner can get from V2G participation reduces the total cost of ownership, therefore the price gap between EVs and ICEs decreases (Lunz, Yan, Gerschler, & Sauer, 2012). In addition, driving an EV is more beneficial for BEV consumers since electricity is cheaper than gasoline. In figure 3, the price of gasoline and the eGallon (electricity) price over time till 2013 is being shown.

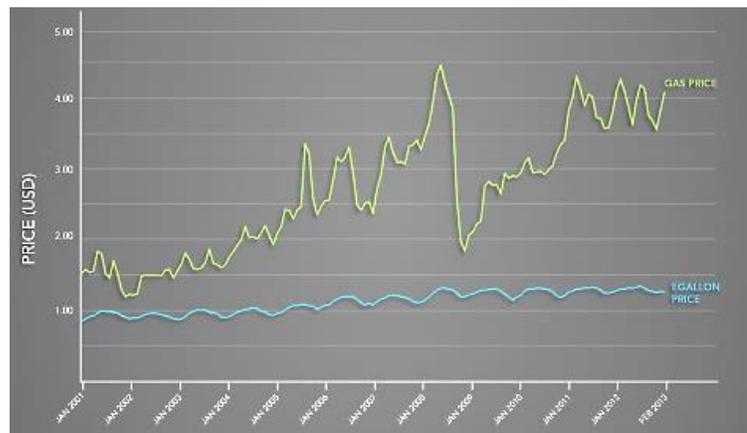

Figure 3. Price of gasoline and eGallon price over time (US Department of Energy, 2013)

Gasoline prices depend on the international markets, so it oscillates through time, but electricity prices are regional and more stable. BEV customers would not need to worry about sudden unpredictable inflations in their fuel prices.

In order to be able to deploy V2G, certain infrastructure will be required which would be expensive to implement. Smart grid is a part of this infrastructure. Amin (2011) introduces smart grid as using computers, and other communicating, sensing, and controlling technologies with an electric power grid. It also shows that the main purpose of smart grid is to improve reliability of delivering electricity, minimize electricity cost for customers, and accelerate the interconnection of alternative energy sources to the grid. In 2007, the United States congress passed the Energy Independence and Security Act setting

specific goals for the development of smart grid in the country. There was an investment of about \$7 billion on smart grid technologies in the U.S. (Amin, 2011). Moreover, devices should be able to operate with bi-directional power flow, and charging devices should communicate with the utilities (Grahn & Söder, 2011). Electric vehicles can be charged overnight at residential homes, or during the day at work or other public charging stations. Charging infrastructure are one of the main part of a V2G system. Electricity as an alternative fuel has lower density compared to gasoline. This causes EVs to have shorter driving range than ICEs (Shukla et al., 2011). Therefore, “drivers of EVs tend to be overcautious when planning their journeys”, which is called “range anxiety” (Tsang et al., 2012). This range anxiety has acted as a barrier to adoption of EVs in a large scale. One solution to address range anxiety is through development of public charging infrastructure (Dong, Liu, & Lin, 2014). As of April 2015, there were 9,428 charging stations equipped with 24,016 outlets in the U.S. (U.S. Department of Energy, 2015).

Different elements form a V2G system such as, power company (grid and utility), aggregators, and EVs, all of which have different effects on its operation (Hosseinpour & Egbue, 2015).

Connecting electric vehicles to the electricity grid may need additional investments in the electricity generation and transmission capacity. Furthermore, there may be intensified wear on transformers, power quality issues, distribution system losses, and voltage fluctuations (Richardson, 2013). According to Kintner-meyer, Schneider, & Pratt (2007), the existing grid capacity in the U.S. is adequate if 73% of the current light-duty fleet consisted of PHEVs. On the other hand, another study showed that if BEVs have a

penetration rate of 25% in 2020 in 13 U.S. regions, and if all of them are connected to the grid at around 5 p.m every day, 160 new power plants are required to provide the extra electricity for those vehicles (Guille & Gross, 2009). This 160 additional power plants are in a case of uncontrolled charging of EVs. However, using V2G and a smart charging and discharging scheduling of EVs, the increased load could be managed. For example, a study with the assumption of 5 million PHEVs in California’s grid showed if charging time is managed and happened during off-peak hours, the extra load would not require installing new generation plants (Sanna, 2005). Figure 4 shows this load during different time of day.

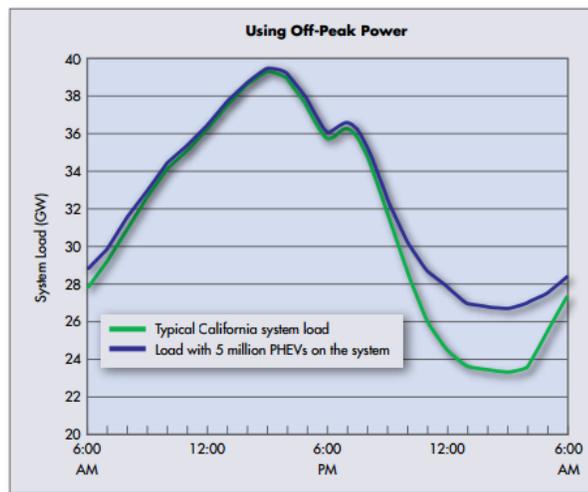

Figure 4. Typical California load vs load with 5 million PHEVs if charging at nights (Sanna, 2005)

Therefore, considering the grid and power company point of view is really important in the operating and scheduling of a V2G system. The next element of a V2G system is the aggregator. An aggregator is an agent that is placed between the power company and EVs in order to control and coordinate their charging and discharging (Lin et al., 2013). It is an actor at the electricity market which manages charging and discharging of electric vehicles, in order to meet the minimum bid at the control power market and

regulation of electricity grid (Grahn & Söder, 2011). In the case of power emergencies, if the grid requests extra electricity, it is the aggregator which takes action and replies to the grid with the increased or decreased charging rates; this is called regulation service. The amount of increase or decrease in charging rates is called regulation capacity (Jin, Tang, & Ghosh, 2013).

The electric vehicle is the other actor and perhaps the most important element in the V2G system. According to Kempton & Tomić (2005), vehicles are being used only 4% of the time for transportation. This shows a 96% rate of availability to be utilized for other purposes such as a vehicle to grid system. Both PHEVs and BEVs can be connected to a V2G system. For electric vehicles to be able to operate in the V2G, or in other words become gridable, they should have three components; a power connection to the electricity grid, a control and/or communication device that allows the grid operators access to the battery, and precision metering to track energy flow (Sovacool & Hirsh, 2009)

With any EV in the V2G system, there is a customer associated. Any decision related to participation of EVs in the V2G system is made by their owners. EVs' availability, and scheduling of charging/discharging are tied to their owners' life pattern, working schedules, and overall behavior, all of which are key factors in the system. Grahn & Söder (2011) believe EV owners are important not only because they are counted as customers of the system, but also stakeholders too, since they should sign a permission agreement for the usage of their vehicles' battery.

According to Sovacool & Hirsh (2009), deploying V2G means 6.5 million less barrels of oil every day. They also showed that if a 15 kW battery is placed in the 191

million cars in the United States, and all of them connect to V2G and simultaneously discharge electricity back to the grid, 2,865 GW electricity will be generated. Although this scenario is hypothetical, this amount of electricity would be two times more than the total capacity of all the generators in the U.S.

2.3 Electric Vehicle Scheduling Problems

2.3.1 Overview

Smart charging and discharging is the term used for intelligent control over the charging and discharging of the vehicles. This means charging when electricity is at its lowest price and demand, and/or discharging when electricity is at its highest price and demand (Richardson, 2013).

Scheduling problems of charging and discharging EVs have been studied by previous scholars. A charging and discharging schedule is a preplanned time series of charging and discharging electricity (Sundstrom & Binding, 2012). Different studies optimized scheduling problems from different perspectives. Most of these studies were focused mainly from the perspective of the electric utilities with less concentration on customer satisfaction (Egbue & Hosseinpour, 2014). As explained before, customers are one of the most important agents in a V2G system. If they are not satisfied, they may not participate in the V2G. Therefore, considering them in the EVs' scheduling problems is of great import. Customer satisfaction is the main focus of this thesis.

Scheduling problems can be both offline (static) and online (dynamic). In the offline problems, it is assumed that all the information is available ahead of time, thus V2G system management are aware of the number and the specifications of EVs going to enter the system. On the other hand, in the dynamic scheduling problems, not all the required information is identified in advance for planning. EVs' flow in the system are not known beforehand, and charging and discharging requests are received over time and at will.

Identifying the optimal scheduling for charging and discharging EVs is key to the success of V2G, as well as encouraging both customers and electric utilities to operate this technology. Previous scholars worked on both offline and online scheduling of EVs' charging and discharging which are reviewed in the next subsection.

2.3.2 Offline Scheduling of Electric Vehicles

There are several papers on offline optimization regarding the technical side of EVs scheduling from a power company's point of view, some of which only concentrate on EVs' charging without considering the V2G system, such as the model by Mets, Verschueren, Haerick, Develder, & De Turck (2010), to minimize peak load and level the whole load profile.

Some other papers used meta heuristic algorithms such as particle swarm optimization (PSO) in modeling the offline scheduling problems (Saber & Venayagamoorthy, 2009, Wu, Chau, & Gao, 2010, Hutson, Venayagamoorthy, & Corzine, 2008). For example, the objective of optimization problem in (Saber & Venayagamoorthy, 2009) was to minimize total running cost including: fuel cost, startup cost, and V2G cost.

In another study (Wu, Chau, & Gao, 2010), the authors proposed a new multilayer framework for V2G system. The contribution of this proposed framework was to introduce the intragrid concept. Furthermore a cost-emission analysis has been developed and solved using particle swarm optimization from a power grid company perspective, with the objective of minimizing the operational costs and emissions as well as to improve system reliability. In the next paper (Hutson, Venayagamoorthy, & Corzine, 2008), the authors applied particle swarm optimization to maximize EV owners' profit.

Some research took into consideration customers' financial benefits along with the technical constraints of the electricity grid. For instance, Honarmand, Zakariazadeh, & Jadid (2014a) developed a nonlinear mathematical program for the offline scheduling problem, considering technical constraints as well as financial constraints.

To summarize, the previous scholars' offline scheduling models were mostly from utility or aggregator perspective, whereas in this thesis scheduling models are developed from customers stand point and to maximize their satisfaction. Moreover, meta heuristic algorithms and nonlinear modeling were the most popular methodologies in the literature, while mixed integer linear programming is the methodology used in this thesis. Furthermore, unlike some of the papers in the literature, this thesis schedules for both charging and discharging of EVs in a V2G system.

2.3.3 Online Scheduling of Electric Vehicles

Just like the offline studies, there are several papers focused on EVs online scheduling that considered the technical side which may have been even overlooked the

V2G system as well as the discharging of EVs. As an example, in (Cao, Tang, Li, Zhang, & Member, 2012), an online optimized EV charging model has been developed to minimize charging cost using a heuristic model to solve the optimization model without considering the discharge of EVs. In (Lin et al., 2013), The authors optimized EV charge and discharge schedules from a utility company's perspective to minimize fluctuation and regulation in demand.

Other than those highly technical scheduling problems, there are some papers which also addressed financial gains. Here, scholars considered the monetary benefits of EV owners and aggregators as well as the technical side of the V2G. Both heuristic and meta heuristic algorithms were used in these studies (Mal, Chattopadhyay, Yang, & Gadh, 2012, Sortomme & El-Sharkawi, 2012, Soares, Sousa, Morais, Vale, & Faria, 2011, Han, Han, & Sezaki, 2010, Jin et al., 2013). For instance, in (Mal, Chattopadhyay, Yang, & Gadh, 2012), the authors proposed a meta heuristic algorithm and tried to schedule charging during the cheapest time and discharge during the most expensive time. As another example, in (Sortomme & El-Sharkawi, 2012), an online V2G heuristic algorithm was formulated to maximize profits to the aggregator. Aggregator's profit is associated with maximum system benefits such as additional system flexibility and low costs to the customers. In another study by Soares, Sousa, Morais, Vale, & Faria (2011), an online particle swarm optimization algorithm was generated from the aggregator point of view to minimize the total generation cost incorporating generation production cost as well as V2G discharge payment. Then, to compare and evaluate this PSO, an offline mixed-integer nonlinear programming was developed and implemented in General Algebraic Modeling

System (GAMS). In the next work by Han, Han, & Sezaki (2010), a centralized scheduling model was developed using dynamic online algorithm, to maximize revenue for the aggregator from regulation services. The aggregator's revenue comes from the cost of charging EVs plus the revenue gained by providing regulation services. The authors of another paper worked on financial benefits, but overlooked the discharging part of EVs (Jin et al., 2013). They studied EVs' charge scheduling problem from the point of view of customers by reflecting both aggregator's revenue and customer's costs and demands. They modeled both online and offline scenarios. Linear programming was developed for the static problem and heuristic algorithms were generated for dynamic problem. This work focused on EV charging and did not address the V2G system and discharging of EVs.

In Honarmand, Zakariazadeh, & Jadid (2014b), the authors proposed a stochastic V2G scheduling model for charging and discharging EVs in an intelligent parking lot. The objective of this stochastic modeling was to maximize the profit of an intelligent parking lot. Another paper by Su & Chow (2012) proposed an online algorithm for optimally managing PHEVs at a parking lot considering customers' preferences and interests. The mathematical framework was developed to maximize the average state of charge of EVs. The V2G system and discharging of EVs have not been contemplated in this study.

In the other work, Pan, Bent, & Berscheid (2012) studied a centralized real time scheduling of PHEVs. First, the offline scheduling problem was mathematically modeled and then four different online algorithms were developed, all of which were heuristic algorithms. The objective function was to schedule EVs' charging with minimum cost. This study was from an EV owner's perspective, but did not consider V2G operation.

To summarize, the previous scholars' online scheduling models were mostly from power company or aggregator perspective, whereas in this thesis online scheduling model is developed from customer perspective to maximize their satisfaction. Heuristic and meta heuristic algorithms were the methodologies which were mostly used in the literature. However those methodologies do not guarantee a local or global optimal solution respectively. Thus, rolling horizon optimization is used as the methodology of online scheduling in this thesis to get an optimal solution. Charging and discharging of EVs are both incorporated in the scheduling model of this thesis.

2.3.4 Rolling Horizon Optimization Approach

Looking at the online EV scheduling studies, it can be seen that almost every one used heuristic or meta heuristic algorithms for modeling EVs dynamic charging and discharging problem. It should be noted that the results of the heuristic and meta heuristic algorithms are not necessarily optimal. Those methods mostly find only a good solution for the optimization problem. There is no guarantee that they will give a global optimal result (Hosseinpour & Egbue, 2015). One of the objectives of this thesis is to get an optimal solution even for the online scheduling problem of EVs. A methodology to use to achieve this objective is the Rolling Horizon Optimization (RHO) approach. Therefore, RHO is utilized in developing the online optimization algorithm in this thesis.

Rolling horizon optimization breaks the dynamic scheduling problem with a long period into simple static scheduling sub-problems with shorter periods. Therefore, RHO

reduces the complexity of the initial dynamic problem (Dishan, Chuan, Jin, & Manhao, 2013). At every period, the current information is used to solve the optimization problem. A rolling horizon problem can be executed in a forward or backward manner. The forward and backward rolling horizon techniques are the same processes; the only difference is that forward approach starts the process from the beginning of the period, while the backward one starts from the end (Al-Ameri, Shah, & Papageorgiou, 2008).

Rolling horizon optimization has been used in different areas including power generation, manufacturing and production planning, health care planning, shipping and logistics, supply chain, and scheduling problems (Nease & Adams, 2014, Moniz, Barbosa-Póvoa, & de Sousa, 2014, Gartner & Kolisch, 2014, Sheng, Lee, & Chew, 2013, Dishan et al., 2013, Al-Ameri et al., 2008). A lot of these studies showed the efficiency of rolling horizon methodology. For example in the work done by Nease & Adams (2014), utilization of rolling horizon optimization decreased the sum of squared errors (SSE) between demand and supply profiles in power generation, meaning a better load-following performance.

Another example is the study by Gartner & Kolisch (2014) in health care industry. They incorporated the stochastic nature of data by using rolling horizon approach. This paper proved that a rolling horizon technique has better results than heuristic algorithms. For instance, waiting time between admissions, surgery time, and patients' stay time in the hospital were reduced significantly after using rolling horizon approach.

Moreover, according to Sheng, Lee, & Chew (2013), the advantages of using rolling horizon are: being less computational challenging, reducing computer memory requirement and solve time, and using newer information in each period.

To our knowledge, there is no published work on the charging and discharging scheduling of electric vehicles in a V2G system using rolling horizon optimization approach. We are applying forward rolling horizon approach to develop our dynamic EV scheduling algorithm in this thesis (Hosseinpour & Egbue, 2015).

CHAPTER 3

RESEARCH METHODOLOGY

3.1 V2G System Specifications

In this thesis, both offline and online charging and discharging scheduling models are developed. EVs in this study are considered to be connected to the electricity grid for charging and discharging in a public charging station, which is a smart parking lot. The objectives of both scheduling optimization problems are to maximize EV owners' satisfaction in the V2G system (Egbue & Hosseinpour, 2014, Hosseinpour & Egbue, 2015).

We consider customers are satisfied if they; 1) make the maximum profit from discharging their EVs 2) charge their EVs at the minimum electricity cost 3) get the minimum difference between the departure state of charge (SOC) and the desired state of charge (Egbue & Hosseinpour, 2014) and 4) switch their EV battery between different charging and discharging modes as little as possible.

In the V2G system considered in this study, EVs enter a public charging station which is a parking lot equipped with EV charging stalls. This parking lot is managed and controlled by an aggregator. The V2G system architecture is depicted in Figure 5. Main components of the V2G system are EVs, aggregator, and the power company.

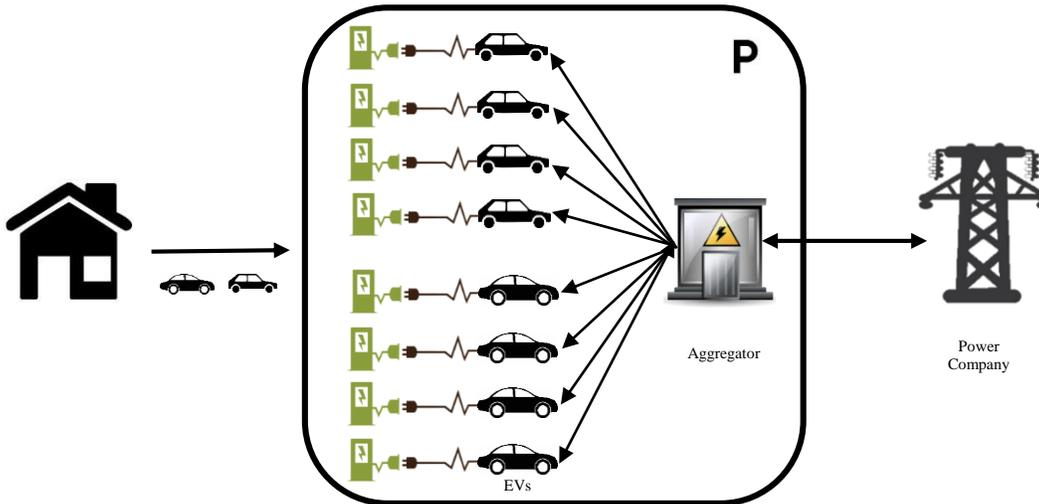

Figure 5. V2G system architecture (Hosseinpour & Egbue, 2015)

In both offline and online charging and discharging scheduling models, three different scenarios are developed. In the first scenario, only EV owners' profit from discharging and cost of charging are addressed in the objective function. So, the model is expected to schedule EVs so that they discharge more than being charged. In the second scenario, unfulfilled charging requests are considered as well as the profit from discharging. Thus, a penalty cost for uncharged electricity is added to the objective function of the second scenario. In the third scenario, a limit is taken into account for the maximum number of switches an EV battery can have, based on its battery age. This limit is incorporated in the constraints of the model. So, the objective function of the third scenario remains the same as the second scenario.

3.2 Offline Scheduling Model

3.2.1 Overview

In the offline problem, all of the information, such as the specification of the electricity grid as well as EVs are known in advance. Assuming that everything is known for the parking lot management ahead of time, a mathematical model is developed for the offline problem. The V2G management can plug all of the parameters of EVs and the grid into the mathematical model and find the optimal charging and discharging scheduling for electric cars.

3.2.2 Model Notations:

As previously explained, the offline scheduling problem is developed in three different scenarios in order to compare the effect of different factors in the optimization model. The indices, parameters and variables used in all the three scenarios are presented below.

Indices:

i EV index

t Time index

Parameters:

a_i Arrival time of EV i

d_i Departure time of EV i

$isoc_i$ Initial state of charge for EV i in terms of electricity units

u_i Desired state of charge for EV i in terms of electricity units

cp_t Electricity capacity in terms of electricity units, available for the smart parking lot to be used for charging EVs in period t

- c_t Price of each electricity unit (in cents) for charging EVs in period t
- p_t Price of each electricity unit (in cents) from discharging EVs in period t
- mr_i Minimum desired number of electricity units to keep in the battery of EV i during discharging
- mc_i Maximum battery capacity for EV i in terms of electricity units
- ba_i Battery age of EV i
- nsw_i Maximum number of switches allowed for EV i

Variables:

x_{it} Binary variable representing EVs' charging. $x_{it}=1$ only if EV i is being charged in period t , and $x_{it}=0$ elsewhere. Since only one electricity unit can be charged to each EV in each period, the value for x_{it} also represent the number of electricity units being charged to the EV i in period t .

y_{it} Binary variable representing EVs' discharging. $y_{it}=1$ only if EV i is being discharged in period t , and $y_{it}=0$ elsewhere. Since only one electricity unit can be discharged from each EV in each period, the value for y_{it} also represent the number of electricity units being discharged to the EV i in period t .

md_{it} Mode of EV i in period t . This shows whether EV is being charged, discharged, or is idle. $md_{it}=1$, only if EV i is being charged at period t ($x_{it}=1$), $md_{it}=-1$, only if EV i is being discharged at period t ($y_{it}=1$), and $md_{it}=0$ when EV i is idle in period t .

z_i Integer variable representing number of unfulfilled electricity units for EV i .

soc_{it} State of charge of EV i in period t in terms of electricity units.

sw_{it} Binary variable representing if EV's battery switched or not. $sw_{it}=1$ only if EV i is switched in period t , and $sw_{it}=0$ elsewhere.

When an EV enters the system, there is certain information that are required to be sent to the aggregator of the parking lot. Arrival time (a_i) will be captured as the time the i th EV entered the charging station. The EV owner provides the parking lot management with the time they will depart the system (d_i), the initial state of charge of the EV ($isoc$), the desired state of charge for the EV when exiting the system (u_i), the battery capacity (mc_i), and battery age (ba_i) of their EVs, along with their desired minimum number of electricity units which the battery should not be discharged below in each period (mr_i). Note that, mr_i is specified by the EV owner to make sure their EV has the minimum amount of charge if they want to depart the parking lot before the estimated d_i .

3.2.3 Mathematical Modeling:

The objective function for the first scenario is explained in equation (1).

$$\text{Maximize (Customer Satisfaction)} = \text{Max (Price of discharging), Min (Cost of charging)} \quad (1)$$

From equation (1), in order to maximize customer satisfaction, EV owners should make the maximum amount of money from discharging electricity back to the grid and pay the minimum amount of money to the utility for charging their EVs. This objective function is described mathematically in equation (2).

$$Max \left(\sum_t \sum_i y_{it} * p_t - \sum_t \sum_i x_{it} * c_t \right) \quad (2)$$

To make customers more satisfied, unfulfilled electricity units (z_i) are added in the second scenario. By unfulfilled electricity units, the author means the difference between the identified desired state of charge of i th EV and the actual state of charge of that EV when departing. Specifying a desired state of charge shows that customers prefer to leave the V2G system having that amount of charge for their EVs. Unfulfilled electricity units are incorporated into the objective function. To normalize it with other cost factors in the objective function, a weight (pc_i) is used. This weight is the penalty cost for unfulfilled electricity units. Based on this new parameter, the objective function for the second scenario is shown in equation (3) and equation (4) below.

$$Maximize (Customer Satisfaction)= \quad (3)$$

Max (Price of Discharging), Min (Cost of Charging), Min (Unfulfilled Charge)

$$Max \left(\sum_t \sum_i y_{it} * p_t - \sum_t \sum_i x_{it} * c_t - \sum_i pc * z_i \right) \quad (4)$$

Note that the objective function of scenario three is the same as scenario two. Therefore, objective function of the third scenario is the same as equation (4).

Model constraints for all three scenarios are explained respectively. The constraint in equation (5) controls the charging and discharging of EVs in the system. Based on this equation, the total electricity units from charging, summed with the unfulfilled electricity units minus the total discharged electricity units should be equal to the desired state of charge minus the initial state of charge of that EV.

$$\sum_{t=a_i: d_i} x_{it} - \sum_{t=a_i: d_i} y_{it} + z_i = u_i - isoc_i \quad \forall i \quad (5)$$

Equation (6) puts a cap on the amount of electricity which can be used for charging EVs in the parking lot. The sum of the total charged electricity units for all EVs in all the periods must be less than or equal to the defined grid capacity. The electricity capacity available for the parking lot to be used in V2G, cp_t , is equal to electricity generation in each period, minus the non-EV electricity demand in that period

$$\sum_i x_{it} \leq cp_t \quad \forall t \quad (6)$$

The state of charge of each EV in every period is calculated using Equation (7). According to this constraint, the SOC in each period for each EV is equal to its SOC in the previous period, plus the amount of charge the EV gained minus the amount of electricity the EV discharged at that period. Equation (8) defines the state of charge for the i th EV in period 0 as the initial state of charge of that EV.

$$soc_{it} = soc_{i(t-1)} + x_{it} - y_{it} \quad \forall i, t \mid t \geq 1 \quad (7)$$

$$soc_{i0} = isoc_i \quad \forall i \quad (8)$$

The following two equations consider a lower limit and an upper limit for state of charge of each EV in each period. According to Equation (9), the state of charge for EVs in each period should not be less than the minimum desired number of electricity units for that particular EV. Respectively, Equation (10) implies the state of charge for each EV in each period should not be more than its battery capacity.

$$soc_{it} \geq mr_i \quad \forall i, t \quad (9)$$

$$soc_{it} \leq mc_i \quad \forall i, t \quad (10)$$

Equation (11) controls charging and discharging of each EV in each period to prevent concurrency.

$$x_{it} + y_{it} \leq 1 \quad \forall i, t \quad (11)$$

According to equations (12) and (13), EVs must not be charged or discharged before arriving at the parking lot or after departing the system.

$$X_{it} = 0 \quad \forall i, t \mid t > d_i \ \& \ t < a_i \quad (12)$$

$$y_{it} = 0 \quad \forall i, t \mid t > d_i \ \& \ t < a_i \quad (13)$$

All the above explained constraints are common in all three scenarios. Scenarios one and two have the same constraints but different objective functions. Scenario three has the same objective function as the second scenario, but, besides all the constraints in scenarios one and two, scenario three has the switching number constraint as well. According to Grahn & Söder (2011), as the number of charging and discharging increased, the battery would exhaust faster. Therefore, as explained above, to make customers more satisfied, a limited number of switches is considered in the third scenario. The maximum number of switches (nsw) for each EV is identified by their battery age. Based on the assumption made, if the battery age is less than or equal to 3 years, the nsw_i is 8. It is less than or equal to 7 years but greater than 3 years, nsw_i would be 7. Finally, if the battery age is more than 7 years, the allowed number of switches is 5. The battery age information, bai , is given by the EV owner to the parking lot upon arrival to the system. Then, based on the battery age and the rules defined above, the nsw_i for each EV is considered. According to

these explanations, the following equations are added as the extra constraints for the third scenario.

Equation (14) determines the mode of each EV in each period. Based on this equation, if $X_{it}=1$, which means EV is being charged, the mode will be 1. Additionally, if the EV is being discharged, meaning $Y_{it}=1$, the mode will be -1. Furthermore, if none of charging or discharging happens (X_{it} and $Y_{it}=0$), it means EV is idle in the system, and the md_{it} will be 0.

$$md_{it} = x_{it} - y_{it} \quad \forall i, t \quad (14)$$

Equations (15) and (16) altogether calculate the switching numbers and determine if switching happened or not. The method used with these two equations is to compare the mode of i th EV at period t with the mode of same EV at the previous period ($t-1$). As the result of these constraints, sw_{it} will be 1, if the mode of EV i is changed at period t , and it will be 0 if the mode of EV i is not changed. Based on the definition of mode and equations (15) and (16), switching happens when EV's mode changes in one of the following ways: from charging to discharging, from discharging to charging, from idle to charging, from idle to discharging, from charging to idle, and from discharging to idle.

$$md_{it} - md_{i(t-1)} \leq BigM * sw_{it} \quad \forall i, t \geq 2 \quad (15)$$

$$md_{it} - md_{i(t-1)} \geq -BigM * sw_{it} \quad \forall i, t \geq 2 \quad (16)$$

In the above calculations, M is defined as a large number. To elaborate more how the model determines if switching has happened ($sw_{it}=1$) or not ($sw_{it}=0$), further explanations are provided below.

Assuming the left hand side of the above inequalities ($md_{it}-md_{i(t-1)}$) is a variable named F_{it} , and based on the previous explanation about values for md_{it} , possible values for F are -2, -1, 0, 1, and 2. Switching happens if F is -2, -1, 1, and 2. Respectively, there will be no switching if F is 0. We should prove that for all possible values of F , the correct switching will be calculated using inequalities (15) and (16).

Starting from $F=-1$, which means EV mode changes from charging '1' to idle '0', ($F=0-1$) or from idle '0' to discharge '-1', ($F=-1-0$).

$$\begin{cases} F \leq M * sw \\ F \geq -M * sw \end{cases} \xrightarrow{\text{If } F=-1} \begin{cases} -1 \leq M * sw \\ -1 \geq -M * sw \end{cases} \xrightarrow{\text{Then}} \begin{cases} sw = 0 \text{ or } 1 \\ sw = 1 \end{cases}$$

As it has just been proved, the first row of the inequality does not find the sw value. According to this inequality, both sw of 0 and 1 are possible. However, the second inequality finds sw to be 1. In other words, the second inequality is correct only if sw is 1. So, if $F=-1$, the constraints (15) and (16) will be used to calculate the value of 1 for sw , as expected.

Now, for $F=-2$, which means EV mode changes from charging '1' to discharging '-1', ($F=-1-1$), sw calculations will run as bellow.

$$\begin{cases} F \leq M * sw \\ F \geq -M * sw \end{cases} \xrightarrow{\text{If } F=-2} \begin{cases} -2 \leq M * sw \\ -2 \geq -M * sw \end{cases} \xrightarrow{\text{Then}} \begin{cases} sw = 0 \text{ or } 1 \\ sw = 1 \end{cases}$$

Similarly to $F=-1$, the first inequality does not find the sw value; both sw of 0 and 1 are possible according to this inequity. Still, the second inequality calculates sw of 1. In other words, the second inequality is correct only if sw is 1. Thus, if $F=-2$, switching will be 1.

Moving to $F=1$, which means EV's mode changes from idle '0' to charging '1', ($F=1-0$), or from discharging '-1' to idle '0', ($F=0-(-1)$), the sw calculations will be as below:

$$\begin{cases} F \leq M * sw \\ F \geq -M * sw \end{cases} \xrightarrow{\text{If } F=1} \begin{cases} 1 \leq M * sw \\ 1 \geq -M * sw \end{cases} \xrightarrow{\text{Then}} \begin{cases} sw = 1 \\ sw = 0 \text{ or } 1 \end{cases}$$

This time, the second inequality does not define the value for sw . It is the first inequality which calculates the sw of 1, as it is expected to be.

The next possible value for F is 2; it happens when EV's mode changes from discharging '-1' to charging '1', ($F=1-(-1)$). This is illustrated by the following calculations.

$$\begin{cases} F \leq M * sw \\ F \geq -M * sw \end{cases} \xrightarrow{\text{If } F=2} \begin{cases} 2 \leq M * sw \\ 2 \geq -M * sw \end{cases} \xrightarrow{\text{Then}} \begin{cases} sw = 1 \\ sw = 0 \text{ or } 1 \end{cases}$$

Again, it is the first inequality which calculates the sw of 1 as it expected to be.

Finally, when $F=0$, which means no changing in modes happens for EVs, and EVs are in the same mode as their previous period; If they were being charged, discharged or idle in the period ($t-1$), they are being charged, discharged and idle in the period t as well. This is the same for other modes of discharging, and idle.

$$\begin{cases} F \leq M * sw \\ F \geq -M * sw \end{cases} \xrightarrow{\text{If } F=0} \begin{cases} 0 \leq M * sw \\ 0 \geq -M * sw \end{cases} \xrightarrow{\text{Then}} \begin{cases} sw = 0 \text{ or } 1 \\ sw = 0 \text{ or } 1 \end{cases}$$

As can be seen in the above, in the case of $F=0$, both sw of 1 and 0 meets both above inequalities and are possible for the model to be calculated as sw . So, these two constraints are not enough for the model to calculate the sw value. The best way of forcing the model to calculate a 0 value for switching when $F=0$ is to use the objective function.

Since we have a maximization objective function, we manipulate the model by adding the switching in the objective function with a negative coefficient. This coefficient is a very small value such as “ ε ”. Having this in the objective function, in the case of $F=0$, the model will choose sw of 0. The modified objective function for the third scenario is demonstrated in equation (17).

$$Max \left(\sum_t \sum_i y_{it} * p_t - \sum_t \sum_i x_{it} * c_t - \sum_i pc * z_i - \sum_t \sum_i sw_{it} * \varepsilon \right) \quad (17)$$

After switching numbers is calculated for each EV using the above explanations, the limit for these switching is defined by equation (18) in the constraints of the model.

$$\sum_t sw_{it} \leq nsw_i \quad \forall i \quad (18)$$

Now that the model is complete, all the objective functions and constraints in all three scenarios are described in detail. The proposed offline mathematical model is solved using CPLEX Mixed-Integer Programming solver in the General Algebraic Modeling System (GAMS).

3.3 Online Scheduling Model

3.3.1 Overview

Unlike the offline model, none of the EVs’ information is identified ahead of time in the online scheduling model. However, the V2G management is aware of all the grid specifications beforehand. But, the parking lot management does not know how many EVs are going to enter the system at each period, when they want to leave the system, how much charge they currently have, and how much electricity they need; it is a dynamic model

which is more realistic compared to the offline model. For modeling this online scheduling problem, the Rolling Horizon Optimization (RHO) approach is used and linked with the mathematical modeling developed before. The RHO technique helps the V2G system to receive EVs' information, period by period, and send this data to the mathematical model in order to get the optimum scheduling for EVs in the system (Hosseinpour & Egbue, 2015). In the next subsection, the developed online scheduling algorithm is described.

3.3.2 Online Scheduling Algorithm

In the online scheduling algorithm, period by period, as EVs enter the parking lot, the aggregator acquires EVs' data. This data includes: EVs' arrival time, departure time, initial and desired state of charge, and EVs' battery capacity. The developed online scheduling algorithm which is based on the RHO approach is described in Figure 6.

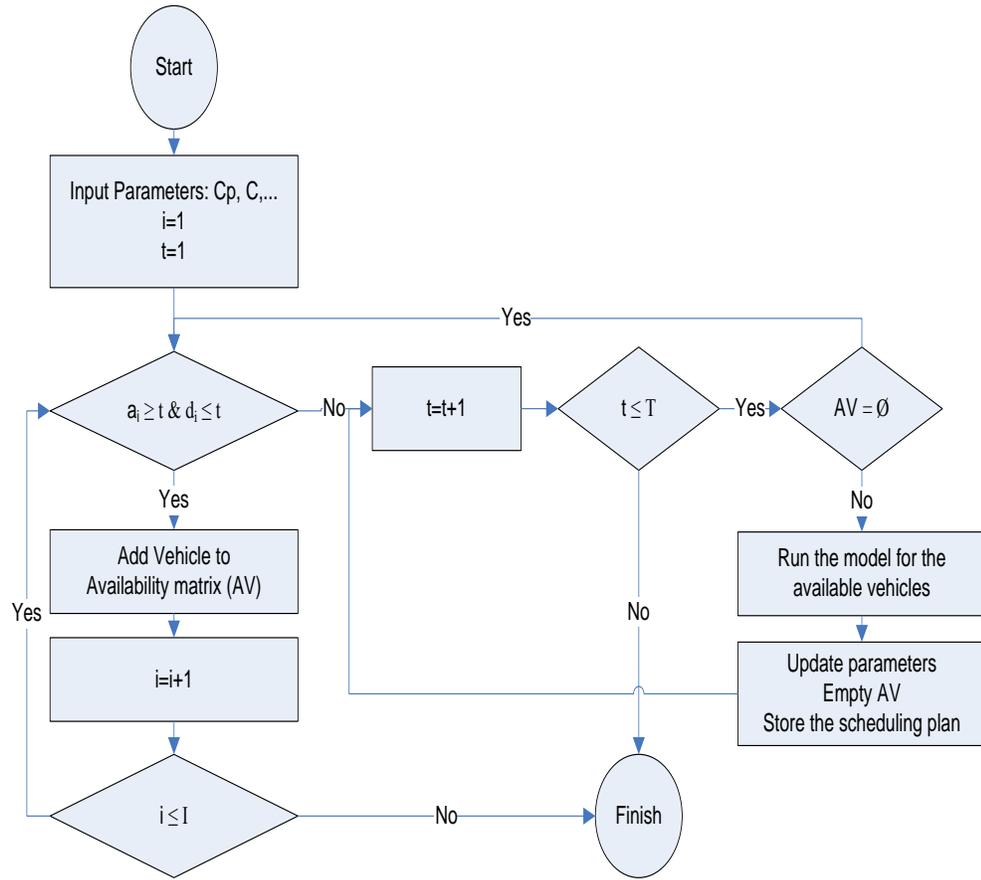

Figure 6. Online scheduling algorithm (Hosseinpour & Egbue, 2015)

The parameters used in the above algorithm are the same as the ones used for mathematical modeling in section 3.2.3. For example, a_i is the arrival time, and d_i is the departure time of EV i . One parameter is added here, AV , which is the availability matrix including indexes associated with available EVs.

The algorithm starts at period 1 ($t=1$). Then, it checks if there is any vehicle available in the system or not. Vehicle availability is defined by $a_i \geq t \& d_i \leq t$. This means the vehicle's arriving time should be more than or equal to the current system time and its departure time should be less than or equal to the current time. If there is no available EV at that specific period, the algorithm moves to the next period. Otherwise, if there are some

available vehicles in the system, the model adds them in the *AV* matrix. The algorithm gets the input parameters of the available EVs and moves to the next available EV at the same period. This will continue through the last EV in the system at that period (Hosseinpour & Egbue, 2015).

In the next step, the algorithm sends the information to the mathematical optimization model to identify the optimal charging and discharging plans for those EVs. The optimization model is the same as the offline scheduling mathematical model described before in the section 3.2.3. As explained before, the mathematical model is considered to be a Mixed Integer Programming with the objective function of maximizing EV owners' satisfaction. Just like the offline mode, three scenarios are considered in the online model as well. After storing the charging and discharging plans for the available vehicles, the algorithm updates the system parameters and makes the *AV* matrix empty again. Moving to the next period, different vehicles enter the system and get their charging and discharging schedules for their duration in the system.

The proposed online scheduling model is solved using CPLEX Mixed-Integer Programming solver in the General Algebraic Modeling System (GAMS), and MATLAB software.

CHAPTER 4

RESULTS

4.1. Numerical Example

To test the efficacy of the proposed offline and online scheduling models, the system of a smart parking lot has been considered and a numerical example is generated respectively. In this parking lot, 500 electric vehicles are assumed to participate in the vehicle to grid system. The model simulation is conducted for one day, 24 hours. System time is divided into 30 minute periods, which results in 48 planning periods $\{1, \dots, 48\}$. Arrival times of EVs in the parking lot are assumed to be uniformly distributed between 6 a.m. and 6 p.m. or period 13 and period 37. Moreover, EVs' departure times are also uniformly distributed between their arrival times and the last period in the system (48). Based on the generated arrival and departure times, parking lot utilization during the 48 planning horizon periods is demonstrated in Figure 7.

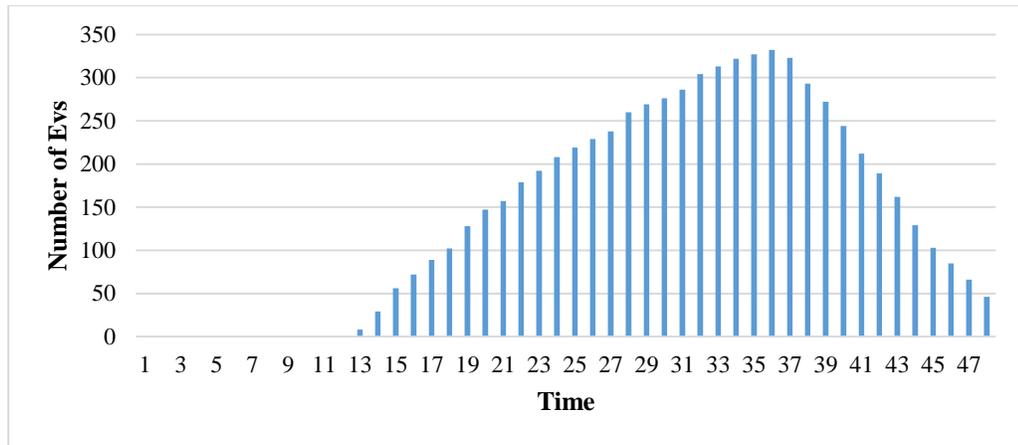

Figure 7. Parking lot utilization

There are three charging levels available for plug-in EVs. The level one charger uses a standard 120 voltage circuit that is typically available in buildings in the United States. If EVs need to be charged at homes overnight, level one charging is the most suitable charging level to utilize (Dong et al., 2014). The advantage of level one charging is that it is already available and no infrastructure investments are required, but it takes longer for a full charge (Grahn & Söder, 2011). The level two charger uses a 240 voltage circuit. It requires a system upgrade for installing level two charging stalls, and it can be employed in public charging stations. The level three charger is the fastest, charging EVs at a very high rate. With a level three charger a Nissan Leaf can be charged to the 80% level of its battery capacity in 30 minutes. Installing level three chargers is very costly, and it requires a lot of infrastructure changes (Dong et al., 2014).

Given the information above, the parking lot in this study is equipped with level two charging stalls (240 VAC, 3.3 kW/hour) for EVs to connect to the electricity network for charging and discharging.

It is important to note that in this study, the electricity for charging and discharging is measured in terms of “electricity units”. Based on 30 minute planning interval considered in this study, and for a level two charging, each “electricity unit” is equal to 1.65 kW per period.

Furthermore, there are two types of electric vehicles participating in the V2G parking lot in this study; BEVs and PHEVs. We assumed that all the PHEVs are Chevy Volts and all the BEVs are Nissan Leafs. Random numbers are generated to specify the types of EVs. Based on the randomly generated numbers, we have 264 PHEVs, and 236 BEVs in our numerical example. According to the U.S. department of energy, Nissan Leaf and Chevy Volt have a maximum battery capacity of 24kWh and 16.5kWh respectively (U.S. Department of Energy, 2011a, U.S. Department of Energy, 2013). Therefore, the maximum battery capacity, mc_i , for BEVs is 15 in terms of electricity units. Accordingly, PHEVs’ mc_i is 10 electricity units.

Next, the minimum desired electricity units retained when discharging, mr_i , is calculated. mr_i values are generated based on the assumption of being uniformly distributed between 1 and 20% of EV’s mc_i . Based on this assumption, the values for mr_i , are 1, 2, or 3 electricity units. And, EVs’ battery cannot be discharged beyond these values. The mr_i frequencies are shown in Figure 8.

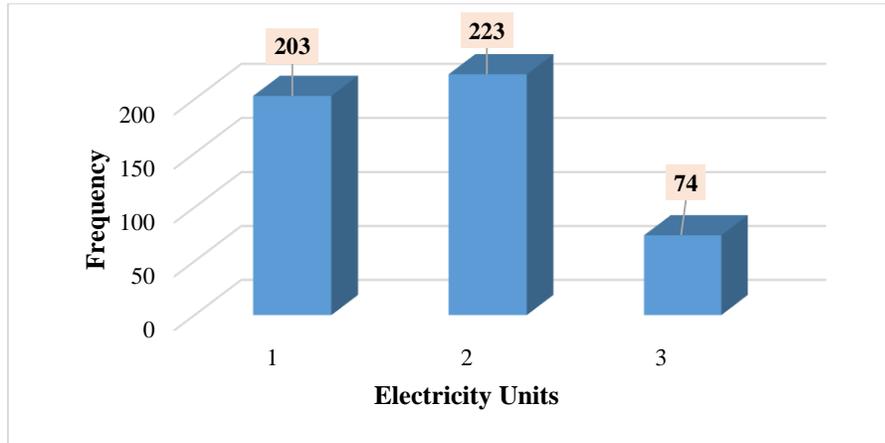

Figure 8. EV mri value frequencies

When EVs enter the parking lot, their battery has a certain level of charge. This level of battery charge, called “initial state of charge” in this study (*isoc*), is assumed to be uniformly distributed between mr_i and mc_i . The values for *isoc* are generated as the minimum of 1 and maximum of 14 electricity units. The distribution of *isoc* values are shown in Figure 9. The EV owners also desire to leave the parking lot with a specific charge level. This parameter, defined as the “desired state of charge” (*u*), is randomly generated as well. *U* values are uniformly distributed between *isoc* and mc_i . The minimum and maximum generated values for *u* are 1 and 15 electricity units respectively. Figure 10 shows the frequency of *u* values.

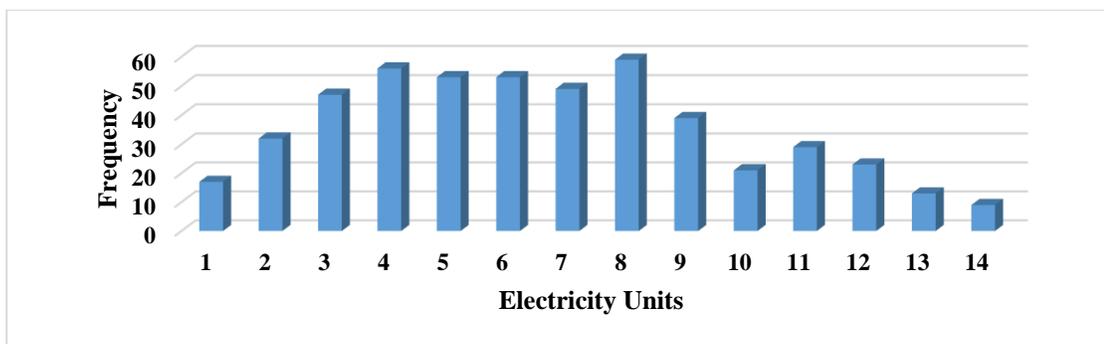

Figure 9. Distribution of *isoc* values

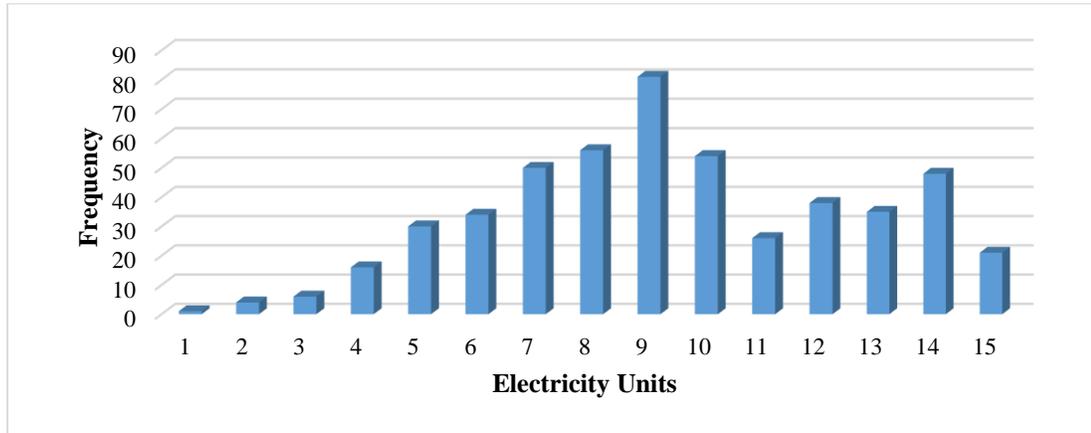

Figure 10. Distribution of u values

Figure 11 demonstrates both $isoc$ and u values at the same time for 50 randomly selected EVs.

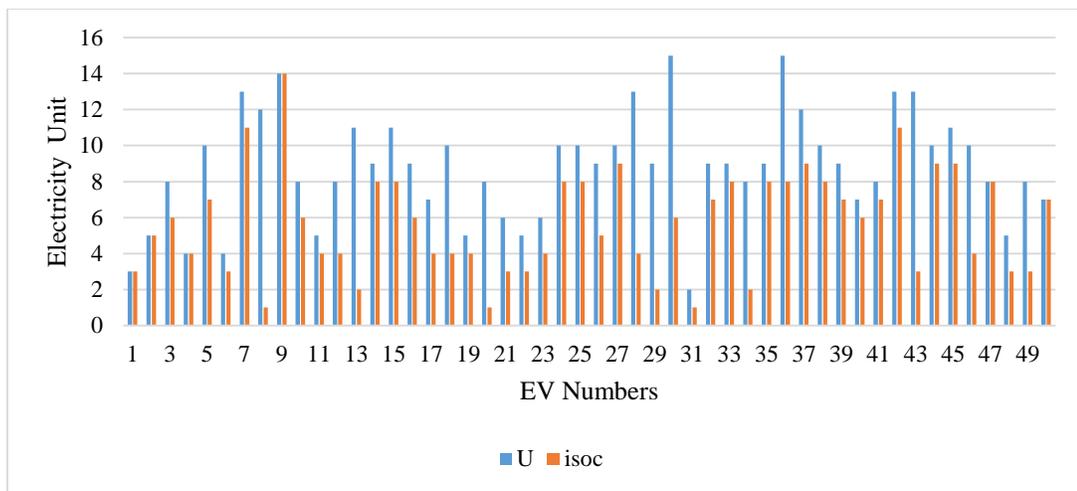

Figure 11. $isoc$ and u values for 50 randomly selected EVs

It should be mentioned that EV owners determine their desired state of charge rationally and based on their duration in the parking lot.

Every EV's battery has a specific age. The battery age for EVs, ba_i , are generated using random numbers between 1 and 10. This parameter is shown in Figure 12.

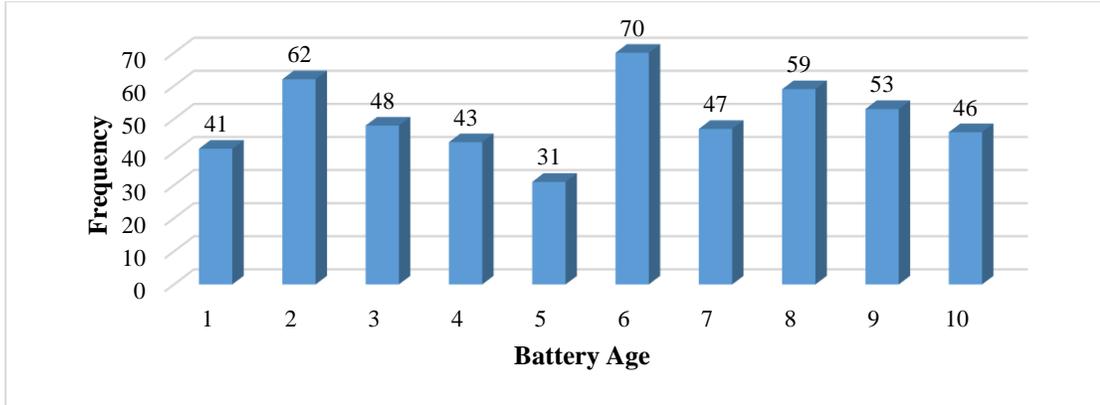

Figure 12. EVs' battery age

There is a maximum number of switches being considered in the third scenario of both offline and online models. This maximum number of switches for each EV, nsw_i , is defined based on EV battery age. Table 1 shows the nsw values based on battery ages.

Table 1. Maximum number of switches

Battery Age	NSW (Maximum Number of switches)
$ba \leq 3$	8
$3 < ba \leq 7$	7
$ba > 7$	5

As shown in the table above, EVs with less than or equal to 3 battery ages have an nsw of 8. For the cars that have a battery age greater than 3, but less than or equal to 7, the EV can be switched 7 times. Finally, for battery ages older than 7 years, the maximum number of switches is 5 times.

C_t , the price of every electricity unit during charging in period t , is extracted from the graph provided in one of the previous studies (Xu, Xie, & Singh, 2010), using Plot Digitizer software. We converted the prices to determine the electricity price in cents and

each electricity unit of 1.65kW per 30 minutes. Furthermore, the price of each electricity unit during discharging in period t , P_t , is assumed to be the same as C_t .

The next grid parameter defined is the electricity capacity available at the smart parking lot to be used for charging EVs. This parameter, which is noted as cp_t , is calculated using equation (19).

$$cp_t = [\text{Electricity generation at period } t] - [\text{Non-EV electricity demand at period } t] \quad (19)$$

Non-EV electricity demand is extracted from the study by Xu et al. (2010) using Plot Digitizer software. According to their study, the maximum load is calculated to be 10 MWh. Considering the maximum electricity load, we assumed that the maximum electricity generation should be higher than the maximum load (10 MWh), and is equal to 10.5 MWh. Also, in this study, we asserted that only 10% of this electricity is available for the parking lot. All cp_t values are calculated in terms of electricity units.

To compare the rationality of the generated values for load, capacity, and price, capacity and load are plotted against time. Figure 13 shows the available electricity units versus the price of electricity units at each period. Figure 14 shows the non-EV electricity demand at each period versus the price of electricity respectively.

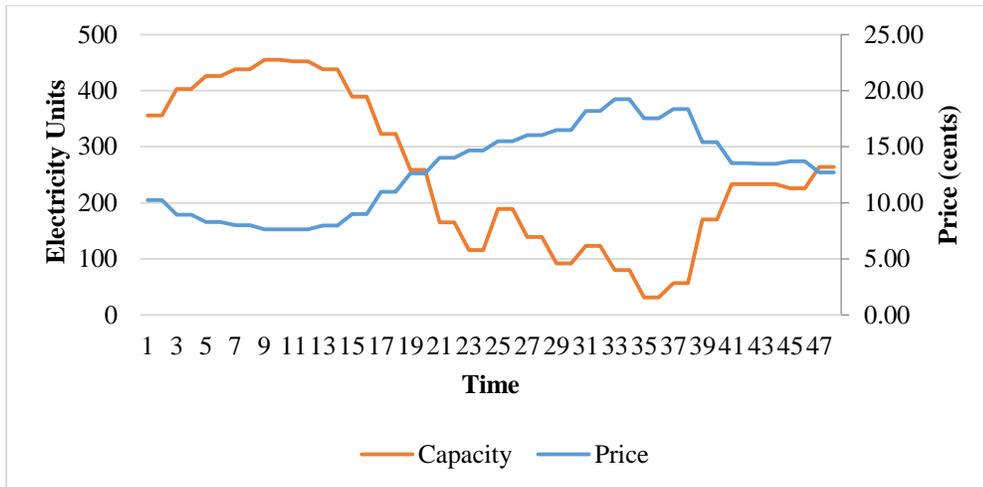

Figure 13. Available electricity capacity vs price of electricity units

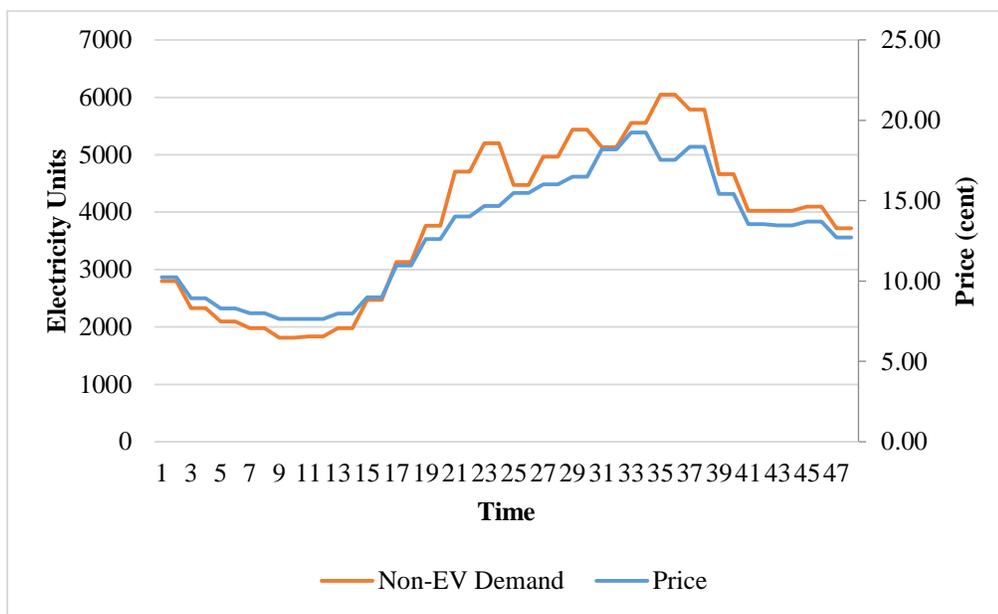

Figure 14. Non-EV electricity demand vs price of electricity units

As it can be seen in the above graphs, whenever the load is higher, the price of electricity goes up as well. Moreover, the price of electricity is lower at the periods when there is more electricity capacity available.

4.2. Offline Model Results

In the first scenario, the objective function is to maximize the money EV owners earn from discharging. No unfulfilled electricity units are considered in this scenario. After running the model, in total, 1,368 electricity units were used for charging EVs, and 3,599 electricity units were discharged back to the grid. As it can be seen, the system schedules more discharging than charging for EV batteries.

There are more discharged electricity units because of V2G management's emphasis on maximizing financial benefits to the customers regardless of the effect of unfulfilled electricity units on their satisfaction. As a result, a large number of customers depart the parking lot without getting their desired state of charge. Moreover, since there is no switching limit in the first scenario, the numbers of switching are high, as expected.

In the second scenario, penalty cost for unfulfilled electricity units is added to the objective function. This parameter, pc , is determined as the maximum price of electricity unit in the planning periods, which is 19 cents. Now that the system includes the desired state of charge of customers, it is expected to have more scheduled charging, compared to the first scenario. The result of running this model shows that altogether, 3,042 electricity units are charged and 1,745 electricity units are discharged in the system. In this scenario, the maximum number of switches is not incorporated in the model. Therefore, there are uncontrolled numbers of switching in this scenario.

In the third scenario, the upper limit of switching is added to the model. These switching constraints limit the maximum number of switches for an EV with respect to its battery age. As previously illustrated in Table 1, the maximum number of switches for the

youngest cars is 8. Thus, we expect the model to function as planned, since this limit is added in the constraints of the model. Figure 15 demonstrates the frequency of different numbers of switches in the different scenarios.

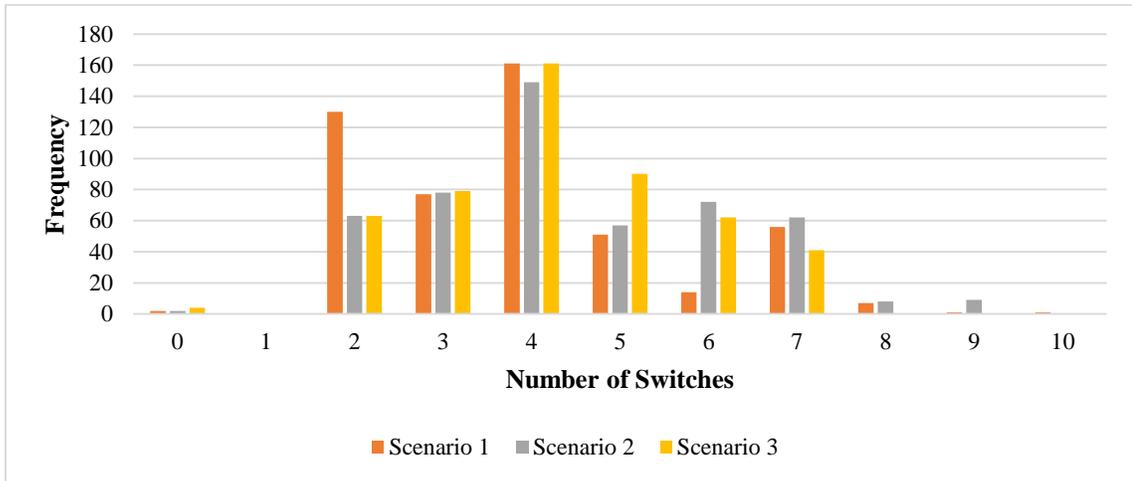

Figure 15. Frequency of number of switches in the offline all three scenarios

Furthermore, there are 3,012 electricity units from charging and 1,723 electricity units from discharging in this scenario, which are very close to the ones in the scenario two. Figures 16 and 17 show EVs charging and discharging comparison for all three scenarios. From these figures, it can be observed that in the first scenario, discharging occurs more often compared to scenario two and three. Also, charging is higher in the second and third scenario compared to the first one.

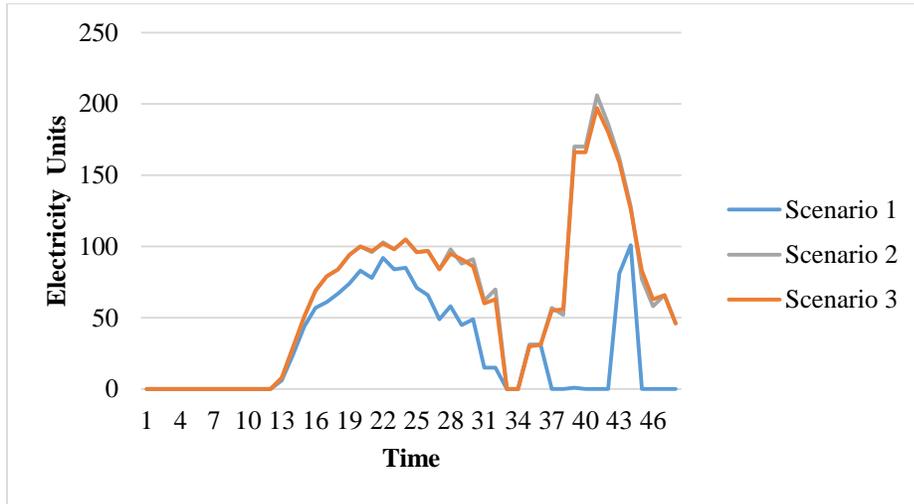

Figure 16. Charged electricity units comparison for all scenarios of offline model

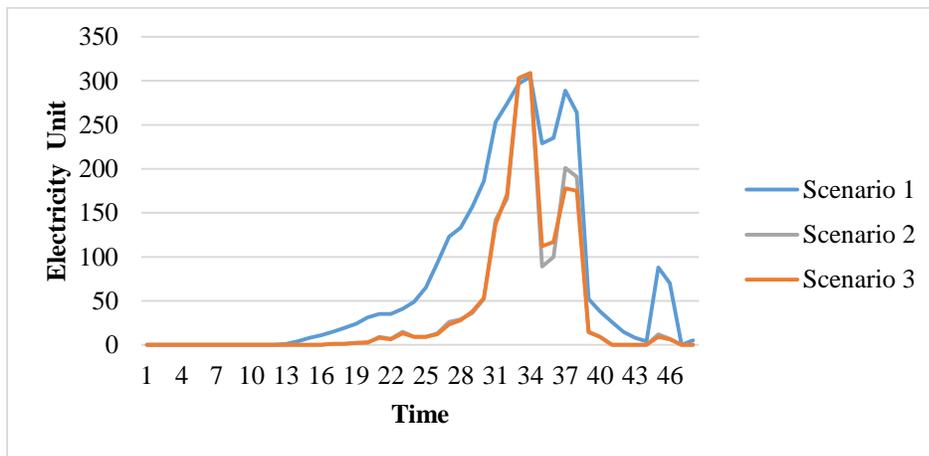

Figure 17. Discharged electricity units comparison for all scenarios of offline model

Figure 18 compares electricity prices with scheduled charging and discharging in scenario three. As intended, it can be observed that charging is mainly scheduled during lower prices of electricity, and discharging happens mostly when electricity prices are higher.

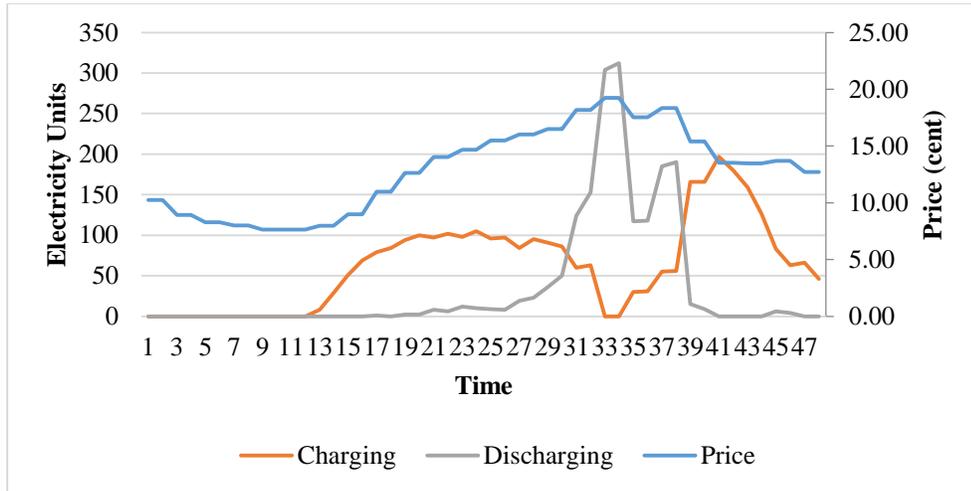

Figure 18. Offline scenario 3 charging and discharging comparison vs electricity prices

Figure 19 shows z values in the first, second, and third scenarios respectively. It can be observed that z values are much higher in the first scenario. In the second scenario, z values for 451 EVs are equal to 0, which means that these EVs leave the system with exactly the desired state of charge. The same follows in the third scenario, which z values are still low, and there are 438 cars with 0 unfulfilled electricity units, which is a little lower compared to the second scenario because of limited number of switches added in the third scenario.

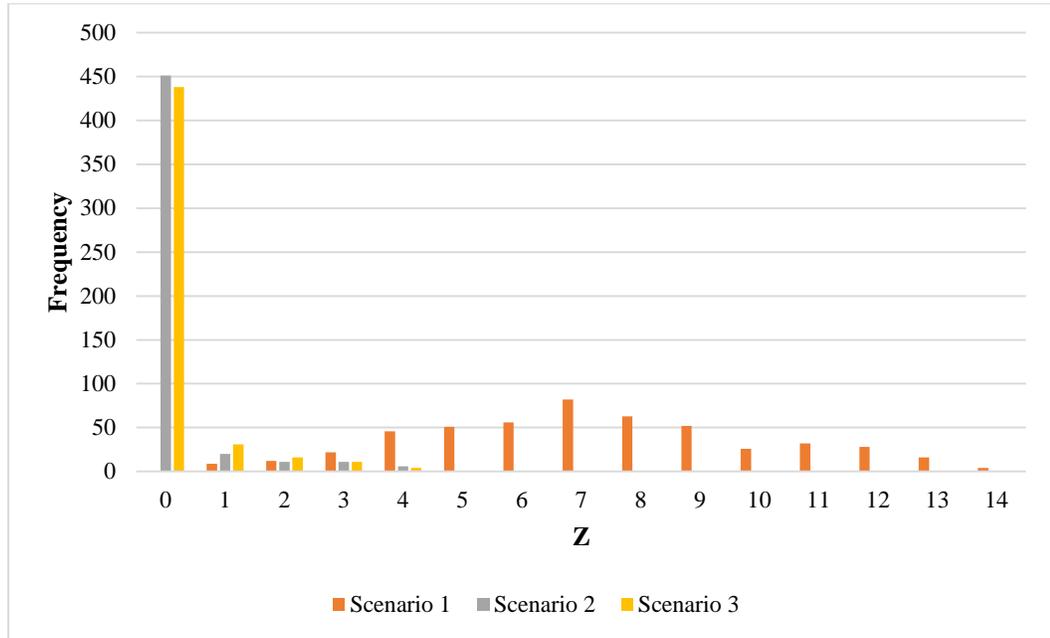

Figure 19. Frequency of unfulfilled electricity units in the offline all three scenarios

To observe and compare unfulfilled electricity units at the same time, Figure 20 shows z values for 50 randomly selected EVs in all three scenarios. As previously explained and shown in this figure, z values for the first scenario are a lot higher than scenario two and three, which have mostly the same z values. In the second and third scenarios, the customers would be more satisfied, since their demand in terms of state of charge are almost met to the desired level.

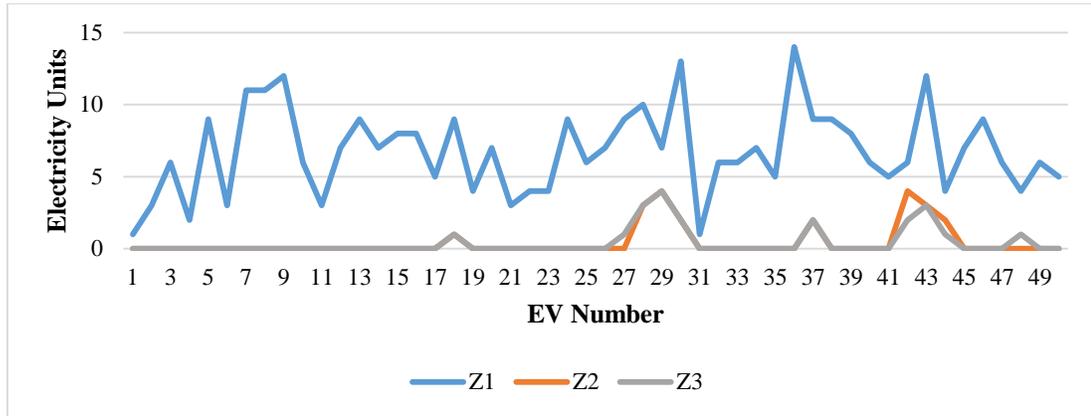

Figure 20. Z values comparison for 50 random EVs in three scenarios of offline model

To observe how the proposed model performed with respect to the capacity, Figure 21 demonstrates charged electricity units in scenario three compared to the available capacity. This figure shows charging never exceeds the capacity, as expected. Also, during some periods with limited electricity available for the parking lot (peak hours), almost all the capacity is used for charging EVs.

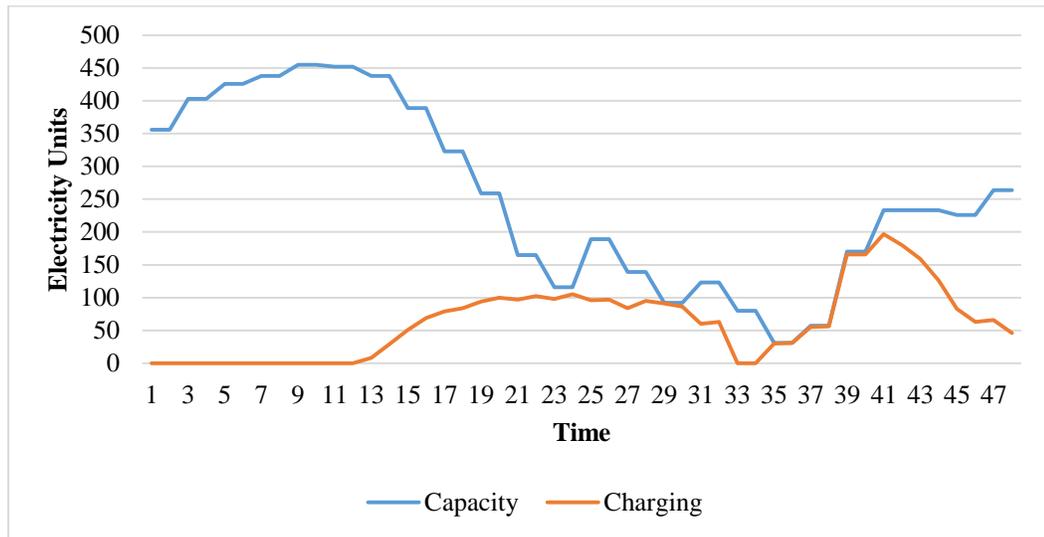

Figure 21. Capacity versus charged electricity units in offline scenario three

4.3. Online Model Results

To solve the online model, MATLAB and GAMS software are linked together. The developed rolling horizon algorithm explained in Figure 6 in chapter 3 are coded in MATLAB. According to this algorithm, MATLAB receives the information regarding EVs in each period, does some analysis on the input data to find out available and ready to schedule EVs, and then sends this information to the GAMS in order to find the optimal charging and discharging schedules for EVs. GAMS is then run, and sends the output back to MATLAB. Afterward, based on the information received from GAMS, MATLAB will update parameters, and move to the next period, repeating the process until all EVs are scheduled in the parking lot.

All three scenarios presented in section 4.3 apply to the online model. Based on the objective function, it is expected that discharging will be scheduled more than charging in scenario one. The output of MATLAB and GAMS show that 1,313 electricity units were consumed for charging EVs, and 3,482 electricity units were consumed for discharging EVs. Not having a penalty cost for unfulfilled electricity units makes a significant number of customers leave the system with a state of charge below what they desired.

In the second scenario, a penalty cost for unfulfilled electricity units is considered. The objective function is the same as scenario two in the offline model. The same as the offline model, pc is 19, equal to the maximum price of electricity unit in the planning periods. With this being stated, it is expected to have more scheduled charging and less discharging compared to scenario one. The result of this model demonstrates 2,973 electricity units of charging and 1,754 electricity units of discharging.

In the third scenario, the objective function does not change and is the same as the second scenario. The difference between second and third scenario is in the switching constraints added to scenario three. Therefore, it is expected to have almost the same total number of charging and discharging electricity units in scenario three and two. The result of this scenario shows there are 2,953 electricity units charged to EVs and 1,747 electricity units discharged from EVs to the grid. If we compare these numbers with the numbers in scenario two, it can be seen they are very close to each other. Both Figures 22 and 23 show EVs charging and discharging comparison in all three scenarios. As explained before, it can be seen that discharging is scheduled more in scenario one compared to scenario two and three, and charging occurs more in the second and third scenario with respect to the first scenario.

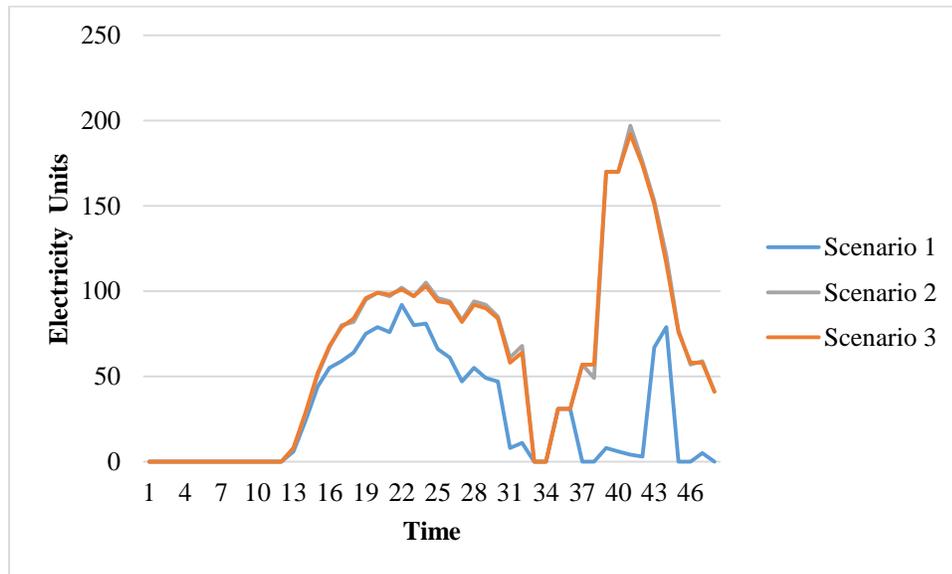

Figure 22. Charged electricity units comparison of all scenarios of online model

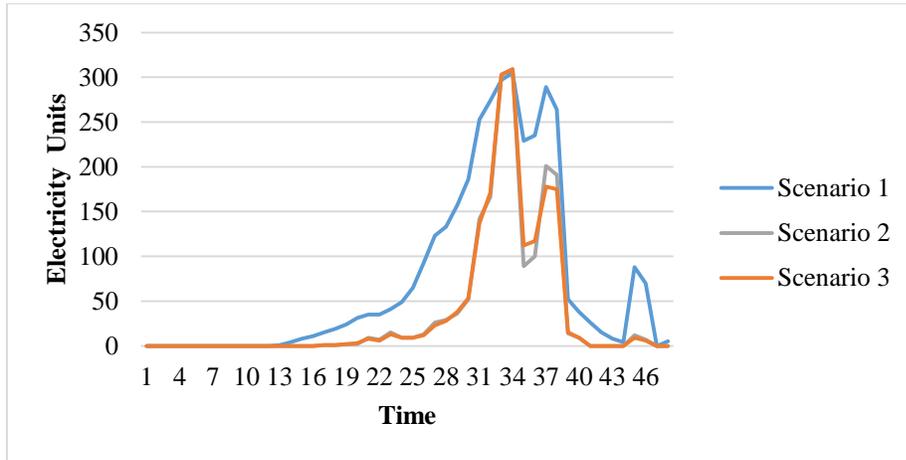

Figure 23. Discharged electricity units comparison of all scenarios of online model

Figure 24 demonstrates z values in the first, second, and third scenarios.

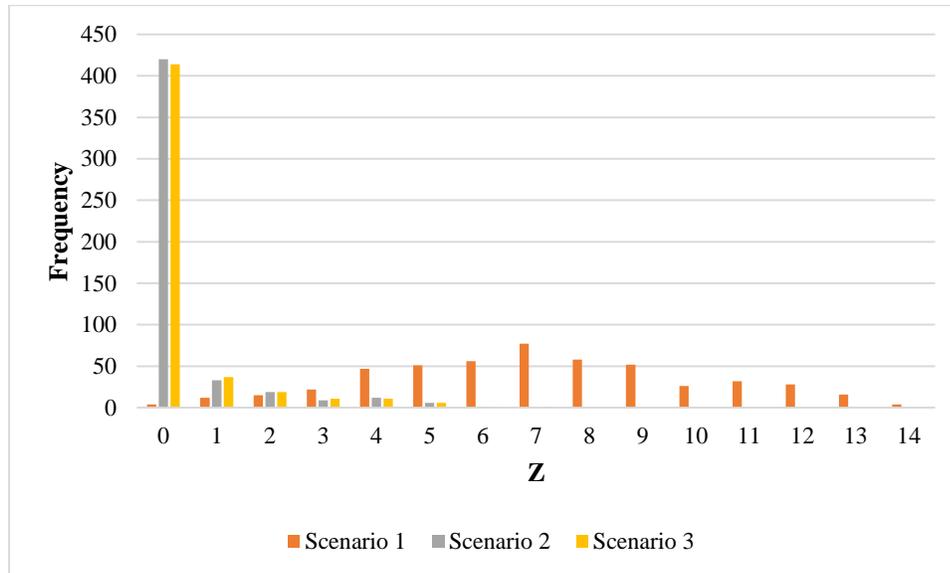

Figure 24. Frequency of unfulfilled electricity units in the online scenarios one, two and three

As shown in the above figures, z values are higher in scenario one. In the second and third scenarios, 420 and 414 EVs leave the system with exactly 0 unfulfilled electricity units respectively.

Figure 25 is plotted to show z values for 50 randomly selected EVs in all three scenarios. As previously explained, z values for scenarios two and three are lower than scenario one, which means a lower level of customer satisfaction in the first scenario.

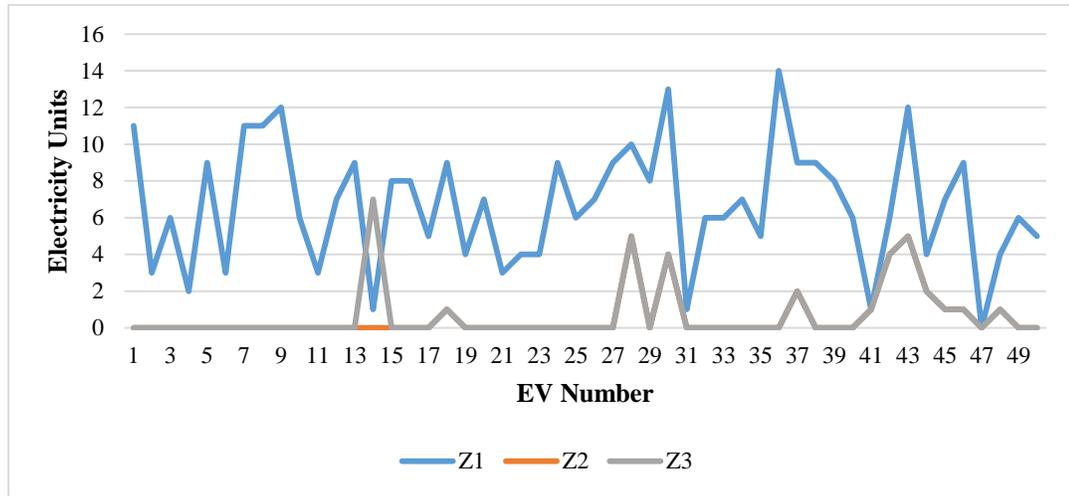

Figure 25. Z values comparison for 50 random EVs in three scenarios of online model

In the next step, we examine the effect of having an upper limit for number of switches in the online model. In the first and second scenario, there is no switching limit in the model, therefore the numbers of switching, sw , are expected to be high. Figures 26 demonstrates the frequency of different numbers of switching in the first, second and third scenarios. As can be observed from this graphs, in scenarios one and two, some EV batteries switch for 13 or 14 times between different modes, which is very high.

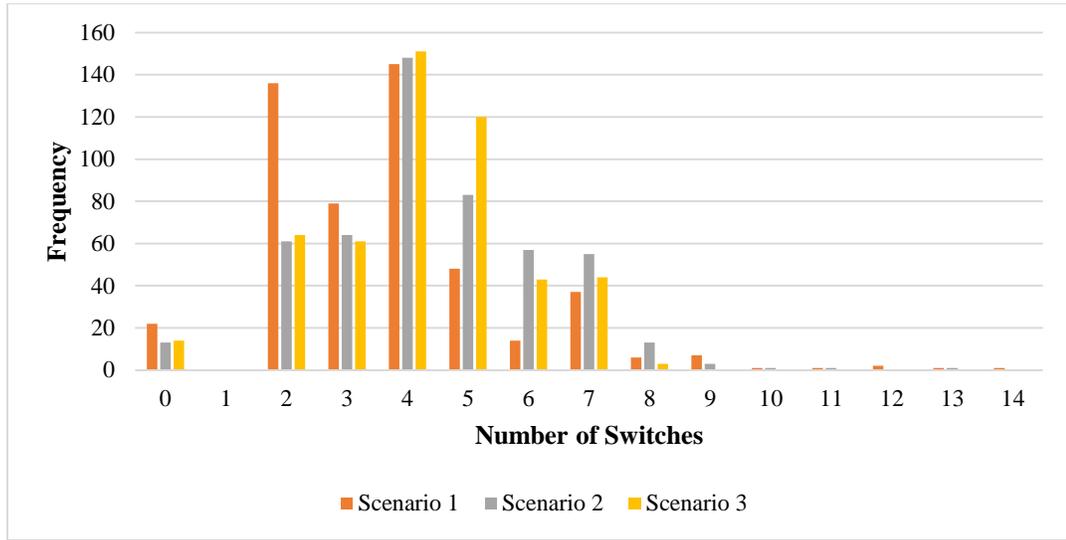

Figure 26. Numbers of switches in online scenarios one, two and three

Furthermore, to test the efficacy of the model, a comparison of electricity prices with scheduled charging and discharging in scenario three is plotted in Figure 27. This figure shows that charging is mainly scheduled during lower prices of electricity, and discharging happens mostly when electricity prices are high.

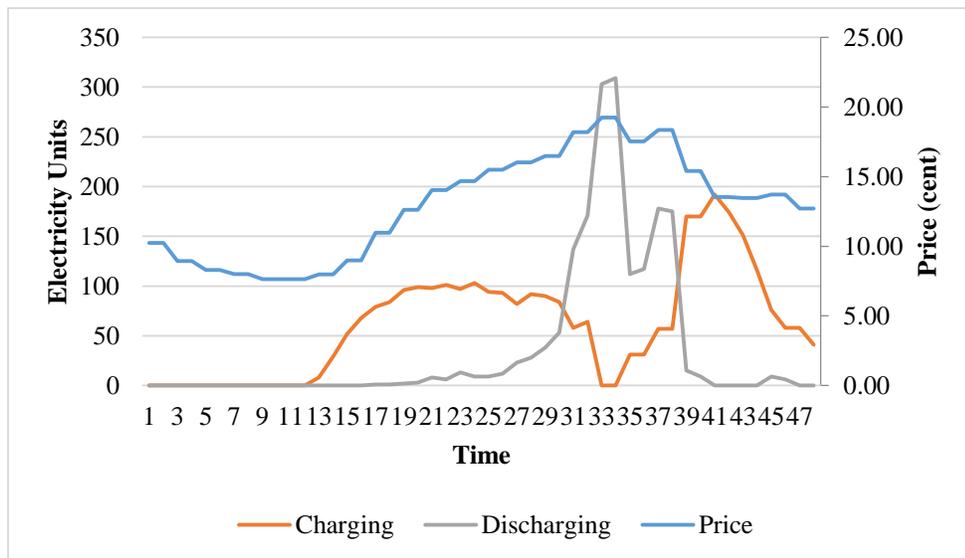

Figure 27. Online scenario 3 charging and discharging vs electricity prices

Moreover, to test the performance of the model with respect to the parking lot's electricity capacity, Figure 28 plots charged electricity units in scenario three versus the available capacity. As expected, this figure demonstrates charging never goes beyond the capacity.

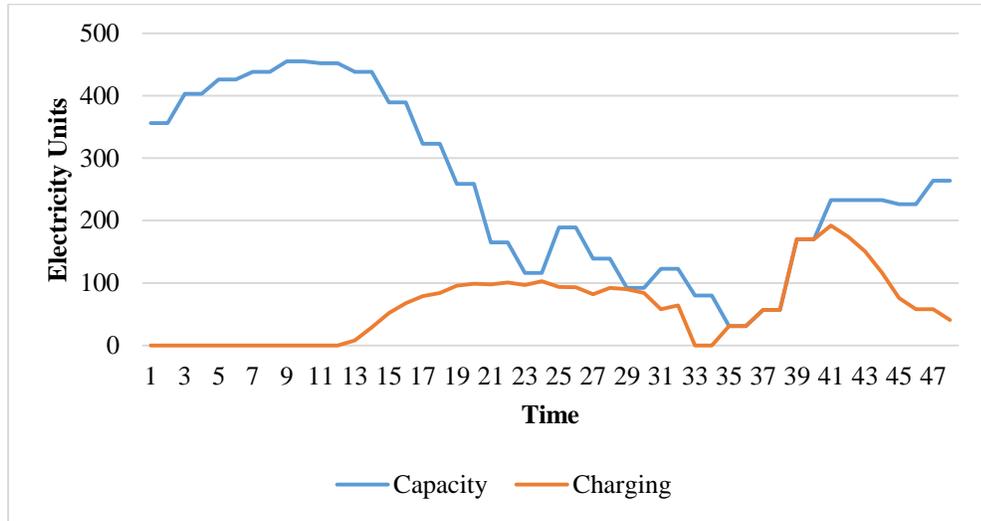

Figure 28. Capacity versus charged electricity units in online scenario three

4.4. Offline and Online Model Comparison

In the offline model, it is assumed that all EV information is known ahead of time; the model solves the scheduling optimization problem considering all EVs information. The output of this model is the optimized solution. On the other hand, in the online model, flow of EVs into the system and their specifications are not identified in advance. In such dynamic problems, heuristic or meta heuristic algorithms are the most common mythologies used. There is no guarantee that the result of these algorithms would be globally optimal, and most of the time, worse than the results of the offline model which is the optimal solution.

In this thesis, rolling horizon optimization approach is applied to the online model instead of heuristic or meta heuristic algorithms. Using RHO allowed the author to link the online algorithm with the optimization tool, which resulted in a global optimal solution. The main reason for applying RHO in this study is to get an optimal solution even if the problem is dynamic. Therefore, it is not expected the results of offline and online models will be very different. To examine the performance of the proposed models, plots of comparing online and offline are developed in this section.

Tables 2 and 3 demonstrate the total number of charged and discharged electricity units in each of the three scenarios for both offline and online models. As table 2 shows, total charging in scenario one for both offline and online models are very close to each other, 1,368 and 1,313 units. The same conclusion applies for scenarios two and three, and for discharging as well.

Table 2. Total number of charging comparison

Model	Total Charging		
	Scenario 1	Scenario 2	Scenario 3
Offline	1,368	3,042	3,012
Online	1,313	2,973	2,953

Table 3. Total number of discharging comparison

Model	Total Discharging		
	Scenario 1	Scenario 2	Scenario 3
Offline	3,599	1,745	1,723
Online	3,482	1,754	1,747

Figures 29, 30, and 31 show offline and online charging and discharging comparison in each of scenarios one, two, and three respectively. As can be observed from these figures, the charging for offline and online are mostly the same in all three scenarios.

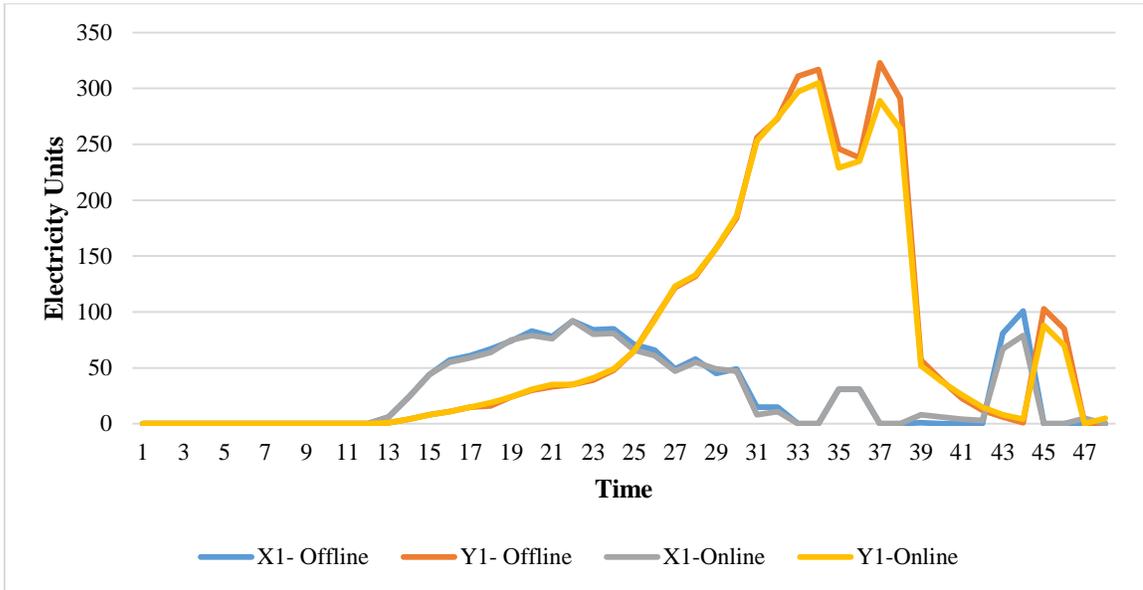

Figure 29. Offline & online charging and discharging comparison in scenario one

As with charging, it can be observed from these figures that discharging for offline and online are also mostly the same in all three scenarios.

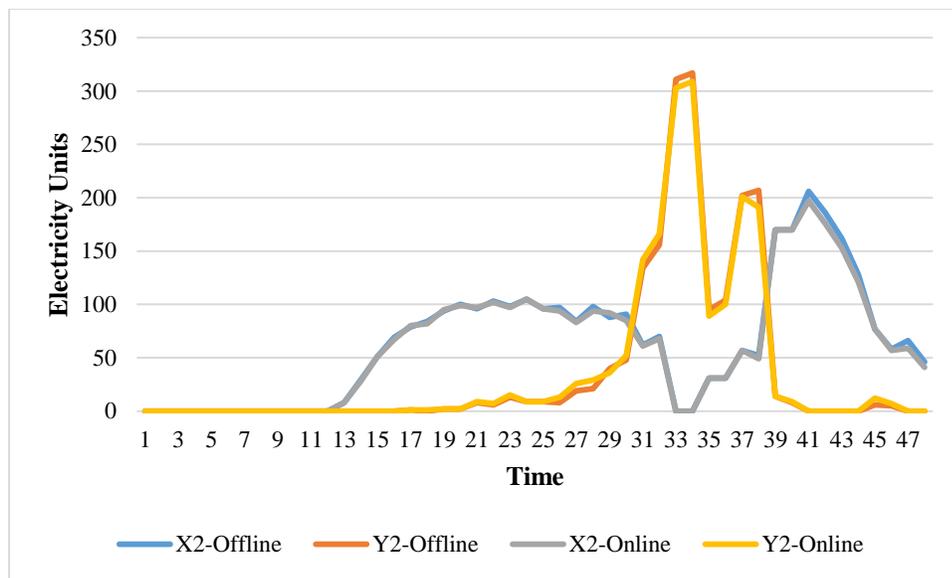

Figure 30. Offline & online charging and discharging comparison in scenario two

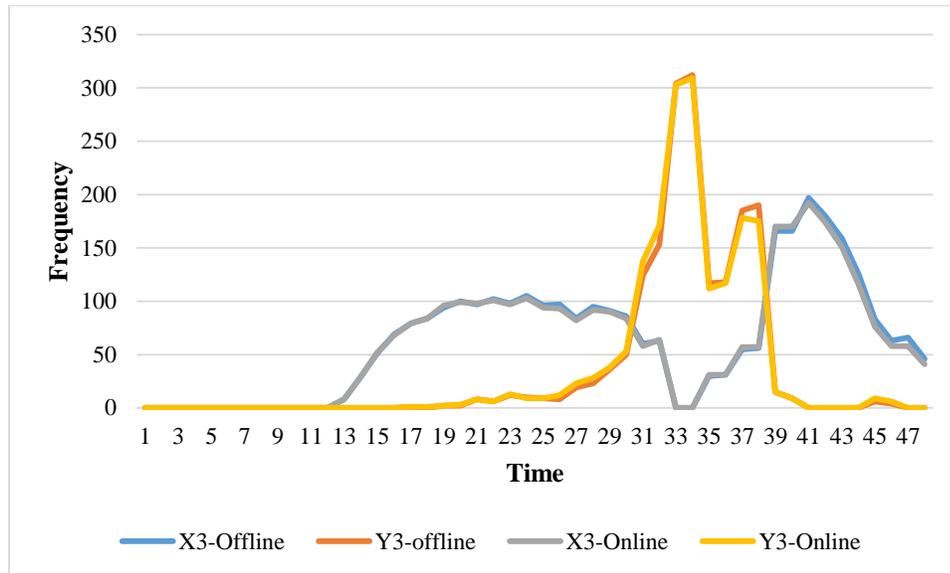

Figure 31. Offline & online charging and discharging comparison in scenario three

Figures 32, 33, and 34 show offline versus online z values for scenarios one, two, and three.

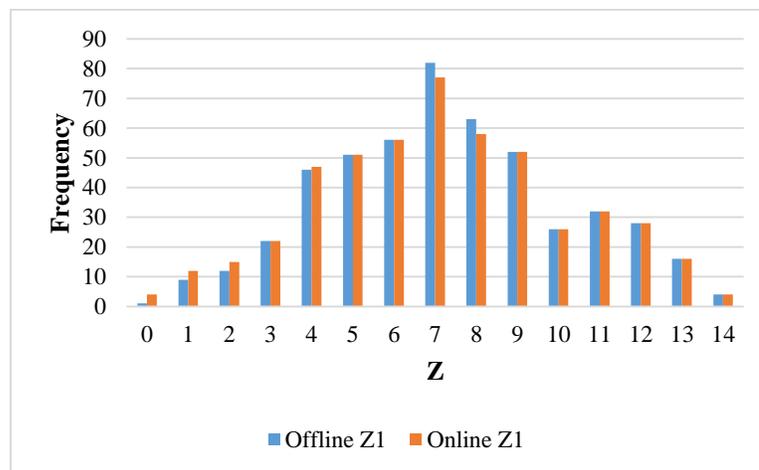

Figure 32. Offline & online Z values comparison in scenario one

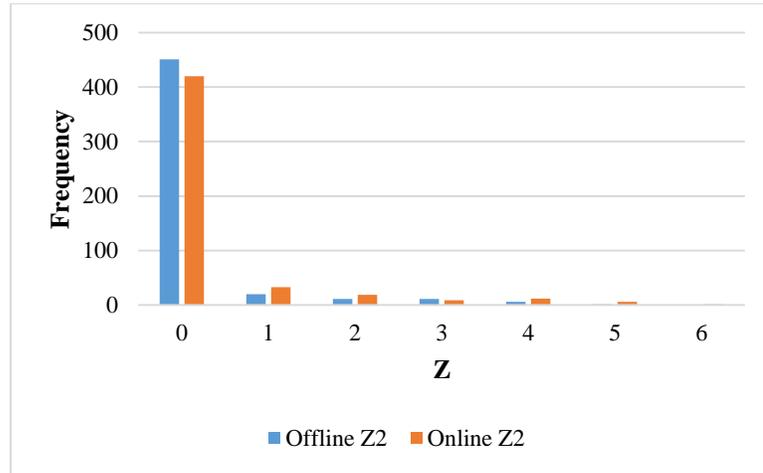

Figure 33. Offline & online Z values comparison in scenario two

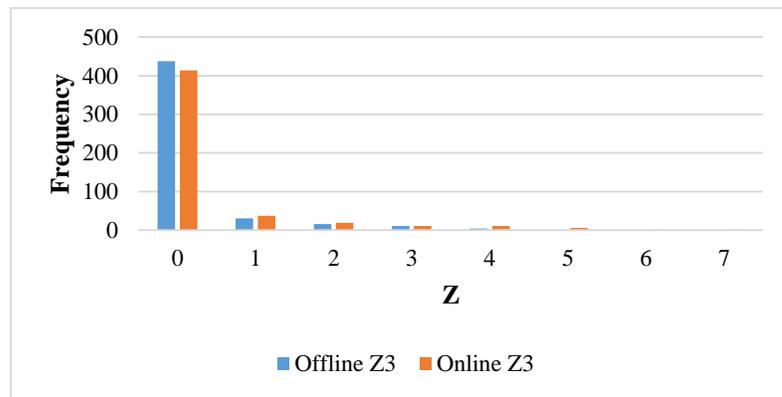

Figure 47. Offline & online Z values comparison in scenario three

As can be observed, z values are almost the same in offline and online models, with the online z values in scenarios two and three slightly higher than the offline model. This can be interpreted as the difference between the online model where the V2G system schedules EVs in one period without knowing what is going to happen next; in the offline model, all the EV information is taken into account.

CHAPTER 5

CONCLUSION AND FUTURE WORK

5.1. Concluding Remarks

One of the potential barriers for large scale EV adoption is the electricity grid may not be ready to handle the extra load EVs would cause in the power network. A technology, which if successfully deployed, would help to manage the additional EV electricity demand in the network is the V2G technology. In this thesis, new EV offline and online scheduling models were developed from the customers' point of view. This is because EVs play the most important role in a V2G system, thus their owners need to be satisfied to be encouraged to participate in the V2G and help the power company and aggregator to achieve their goal of leveling the electricity demand. In the proposed models, using different scenarios and incorporating different factors, the customer satisfaction was maximized.

The offline model was developed in the case that all the information was imported in the model, and the scheduling was determined by considering all the required parameters. However, in the online model, EVs information is not revealed before they enter the V2G system, therefore they could not be considered in the schedule planning. EV data is added to the system as they enter the parking lot. So, when deciding the charging and discharging schedules for a particular EV at a specific period, the V2G management is

not aware of the information of any subsequent EVs entering the charging station. An objective of this study was to examine the efficacy of the Rolling Horizon Optimization approach used for the online model to identify how different the results of the online model were from the offline one. Based on the results discussed in chapter 4, it was demonstrated that the online model results are optimum and very close to the offline model. This is a better performance compared to other online methodologies such as heuristics and meta heuristics algorithms which do not guarantee an optimal solution.

5.2. Future work

This thesis discussed offline and online charging/discharging models for electric vehicles from the customers' perspective. Here, the numerical example data is generated using statistical functions, and tried to be as rational as possible. To incorporate more of a customer point of view to this work in the future, potential EV customers should be studied carefully, customer profiles need to be created, and their attributes and behaviors should be considered in the model as well as the numerical example section. For example, arrival times, departure times, state of charge, desired level of battery charge, and other parameters should be calculated based on customers' daily working commute and driving patterns.

Also, since PHEVs can use other fuels, prioritizing BEVs over PHEVs would be the other consideration in the future work. Moreover, it could be included in the model to prioritize EVs based on their initial and desired state of charge. The current models developed in this thesis are deterministic; therefore future research can develop a stochastic modeling and programming of the scheduling problems
